Anatomy of a Smooth Transition: A Task-Based Macroeconomic Model of AGI Displacement with Fiscal and Social Safety Nets

Abstract

As a transparent thought experiment, this paper models an economy where artificial general intelligence (AGI) enters new-task creation itself, so the engine reinstating displaced labor can collapse endogenously. We build a two-layer task model whose reinstatement rate declines as AI capability advances, with nominal rigidity, the zero lower bound and debt-deflation, capital-tax financing, and a social-instability channel independent by construction, all results conditional on the stated law and declared settings. Under full substitution, automation keeps exceeding labor's capture of new tasks, driving market employment monotonically to zero without self-correction; a high market-employment endpoint is inadmissible, the counterfactual where full substitution is not reached. The piecewise-smooth fast subsystem exhibits a persistence-type boundary equilibrium bifurcation with a closed-form critical reinstatement rate, while the global outcome is a different bifurcation. With public employment as full absorption under the within-period fiscal constraint, the model admits two basins: a crash, or a smooth transition with zero residual unemployment and consumption above the floor, separated by two explicitly modeled gates, a fiscal gate on the consumption floor and a social gate combining a social-instability threshold with an adjustment-speed floor. A bisection locates the fiscal boundary at $g_A = 0.095$ under $\tau = 0.15$; at higher tax rates consumption stays above the floor at every admissible speed and the operative boundary is the adjustment-speed gate near $g_A = 0.14$, a minimum transition time rather than a Laffer limit. A same-budget comparison that reserves revenue for transfers and runs a genuine positive transfer flow contracts the frontier, while the workfare-first transfer buffer does not move it. On the

smooth path at $g_A = 0.010$, minimum consumption is 0.407, public employment ends at 0.85 and residual unemployment is zero, while the fixed corner holds 0.357 and the no-policy path crashes at 0.057. Three magnitudes use U.S. data; the rest are declared and the grid minimum grid-dependent, not identified. The conditional message: a smooth transition requires both a financed fiscal base and a transition speed society can absorb, given automation speed. *JEL classification:* E24, E31, E62, J64, O33.

---

1. Introduction

Artificial general intelligence (AGI) and large-scale automation portend a fundamental reallocation of work. Task-based analyses of recent automation show that new-task creation has historically reinstated labor displaced by machinery (Acemoglu–Restrepo) [2], but the AGI setting is different in kind: AGI participates in *new-task creation itself*, so the reinstatement engine may collapse endogenously. The recent AGI macroeconomics literature splits into two poles. On the *supply side*, Restrepo (2025) [29] and Korinek–Suh (2024) [22] characterize conditions under which automation collapses wages: when the complexity of tasks humans can perform is bounded and full automation is reached, or when automation outruns capital accumulation. On the *demand side*, Fornaro–Wolf (2026) [15] stress that automation shifts income from high-MPC workers to savers, weakening aggregate demand and lowering the natural rate. Yet within this recent literature the two poles are typically treated separately, and the wage-collapse question is not, to our knowledge, joined to the *transitional fiscal policy* needed to sustain demand while the labor share vanishes.

This paper proposes a task-based macroeconomic model that closes these gaps in a single, numerically solvable switching system. The model is offered throughout as a transparent conditional mechanism rather than a forecast. The substitution law, the financing rules and the social parameters are stated explicitly, and strong words such as “must”, “zero” or “unreachable” describe what follows inside the model under those assumptions, not unconditional predictions about any actual economy or normative prescriptions; the policy content is the set of conditions under which the model produces a smooth rather than a

collapsing path. Its ingredients are: a two-layer task model (production and creative tasks) in which the reinstatement rate is driven down endogenously as AGI capability advances, with policy able to offset that decline; a demand side with nominal rigidity, the zero lower bound, and debt-deflation; a fiscal closure in which a capital tax finances workfare (public employment) and transfers under a balanced-budget constraint; and a social-instability channel that is independent by construction rather than an empirically separated series, a separate equation in which a large purely-relief population generates social pressure. Under full substitution the model implies that market employment is displaced to zero, so the operative question is not whether a high market-employment branch survives but whether the fiscal base can expand fast enough for public employment to absorb the workers the market releases. Because the system couples a slow fiscal layer to a fast employment layer, no local linearization can answer that question, and the transition is posed first as a fast-subsystem bifurcation and then as a global outcome bifurcation.

Why a conditional model still carries urgency. We do not assert that full substitution is inevitable, and nothing in the analysis assigns it a probability. The case for taking the scenario seriously now rests on three features that do not require certainty. First, the premise is a live rather than a remote possibility. Retrieval-resistant benchmarks such as the graduate-level GPQA set measure exactly the cognitive and research tasks that define the model's task boundary [47], frontier performance on these benchmarks has risen sharply within a single year [46], and autonomous systems now execute end-to-end research workflows [48]; the distance to the modeled regime is therefore shrinking rather than fixed. Second, the consequences are strongly asymmetric. On the model's own paths the crash basin carries minimum consumption down to 0.057 against a floor of 0.30, while the smooth basin holds it at 0.407, a gap that is large and falls on the same households regardless of whether the scenario was judged probable in advance. Third, and most important for timing, the instruments that decide the outcome are slow-moving. The fiscal base, the capital-tax rule and public-employment institutions take time to build, and the model's central result is a race between that slow accumulation and the faster displacement process; their value is precisely that they are in place before the threshold, not after. This is the logic of preparedness rather than prediction, the same logic that gives climate scenarios and financial stress tests their

policy weight even though none of them forecasts an inevitable event. The contribution of the thought experiment is to identify which conditions move the economy between the two basins and where the boundary lies, knowledge that is useful only if it is available while the slow instruments can still be moved.

Our analytical results are six. We prove that reinstatement collapse drives the labor share monotonically to zero with no self-correcting mechanism (Theorem 1); by the task-accounting identity of the model, the value of skill retention is proportional to the reinstatement rate ω, vanishing as $\omega \to 0$. We upgrade Fornaro–Wolf's demand shortfall into an explicit, decidable deflationary spiral (Theorem 5), cascading the wage-collapse source into crash dynamics. We verify computationally that a consumption-smooth region is nonempty and characterize the welfare-determined capital tax τ^* under an explicit decay assumption, with the numerical financing peak leaving the Laffer ceiling non-binding (Propositions 7–8), and show public employment strictly dominates transfers within a given budget because $1 > \mu_{TM}$ (Proposition 9). We prove that, under the assumed social-pressure law, workfare has a structural protective advantage over a pure unemployment transfer against social-instability risk (Proposition 10), and establish a robustness ceiling for the entire buffer family: beyond a critical shock intensity, no combination of workfare and transfers can prevent an economic crash, so strong shocks require supply-side structural measures (Proposition 11).

Beyond these switching-system results, we develop an analytic bifurcation theory that makes the collapse mechanism itself tractable (Section 4). Deriving the fast subsystem directly from the model, we show that its vector field is quadratic and that the high-employment branch reaches and crosses the switching manifold through a persistence-type boundary equilibrium bifurcation in a frozen static slice, for which we derive a closed-form critical reinstatement rate and then make that rate endogenous to public employment, workfare and retraining. Because the high-employment branch presupposes a reinstatement rate that full substitution rules out, it is treated as a counterfactual rather than a reachable endpoint. The global analysis is therefore stated separately: under a full-absorption public-employment policy the outcome is a two-basin bifurcation between economic collapse and smooth absorption, with a critical frontier speed found by bisection, and geometric singular perturbation theory is used to characterize the finite-rate lag of the fast employment variable relative to the slow

fiscal layer. On a full path the verified effect of an effective fast-subsystem crossing is a discontinuous flattening of the labor-share decline rather than interior convergence, and the distinction is stated explicitly in Section 4.

We anchor three magnitudes to U.S. data (the consumption floor, the transfer MPC $\mu_{TM} = 0.50$, and the workfare wage ratio), set the remaining entries by explicit convention, including the capital-tax growth inhibition $\eta = 0.40$, and run the full battery of experiments under a unified engine (Section 5). On the reported grid the minimum-loss point is a corner solution (workfare-dominant, transfers closed, minimal sufficient capital tax) whose coordinates are grid-dependent rather than identified, and at the baseline frontier growth $g_A = 0.010$ no-policy and pure-transfer regimes are infeasible because they leave the floor unfunded and trigger the modeled MPC-leakage and social channels (Table 3); the smooth full-absorption outcome is itself conditional on g_A, with the critical value near 0.095 under $\tau = 0.15$ (Section 5). No parameter is estimated here, and none of the critical values is presented as one: the critical reinstatement rate of the fast subsystem, the interior workfare share p_E^*, and the global absorption boundary are dimensionless outputs of the calibrated model, so the paper claims structural insight rather than external identification. The central message, read as a model-implied rather than a universal claim, is that under full substitution a smooth transition requires public-employment absorption, and that within the model this absorption has to be financed by a fiscal base that keeps pace with the disappearing market wage.

The remainder of the paper is organized as follows. Section 2 lays out the model. Section 3 derives the analytical propositions. Section 4 develops the analytic boundary equilibrium bifurcation theory. Section 5 presents the calibration and the numerical evidence. Section 6 situates the contributions relative to the literature, and Section 7 concludes.

2. The Model

2.1. Environment

Discrete time $t = 0, 1, \ldots, T$. A continuum of labor $L^S = \bar{L} = 1$ is supplied inelastically and the wage is the numéraire, $w = 1$. Three agents populate the economy: firms that produce with a task technology; a government that taxes capital income and runs transfers / public

employment; and households that consume, save, and supply labor. This is a deterministic switching system of aggregate difference equations (neither a DSGE nor an agent-based model) with no stochastic shocks along the baseline path (Table 5 adds a frontier-growth shock ensemble as a robustness check); all state variables are deterministic time-indexed arrays.

The state variables are the automation threshold I_t, the upper bound of new tasks N_t, the labor-task share $n_t \equiv N_t - I_t$, employment L_t^D, the labor share of employment $s_t \equiv L_t^D/\bar{L}$ (called the labor share throughout; it equals the wage-bill share $w_t L_t^D/Y_t$ only while $w\bar{L} = Y_t$), the price level P_t, nominal debt D_t, real debt $b_t \equiv D_t/P_t$, a skill stock σ_t, and a social-pressure index ς_t.

2.2. Technology: a two-layer task model with an endogenously collapsing reinstatement engine

We extend the Acemoglu–Restrepo task framework to two layers: a production-task layer and a creative-task layer that can itself be automated.

Automation (displacement) frontier.

$$\mathrm{d}I_t^{auto,g} = \kappa_I \, A_t, \qquad A_t = A_0(1+g_A)^t. \tag{1}$$

Reinstatement (new-task creation) engine.

$$\mathrm{d}N_t = \kappa_N^h \, S_t^h + \kappa_N^{AI} \, A_t \, M_0, \qquad S_t^h = S_0 \max\{0,\, 1 - \lambda_h \, I_{t-1}/N_{t-1}\}, \tag{2}$$

where S_t^h is creative labor still performed by humans and κ_N^{AI} governs AGI participation in new-task creation.

Endogenous reinstatement rate. Labor and AGI compete for the new tasks. Let the log capability gain be $g_t = \ln(A_t/A_0)$ and let Γ_t be the policy reattachment stock built by public employment, workfare and retraining, defined in equation (23). The share of new tasks accruing to labor obeys the competitive logistic (discrete-choice) law

$$\omega_t = \Lambda(\ell_0 + \Gamma_t - \beta_A g_t)\,, \qquad \ell_0 = \ln\frac{\omega_0}{1-\omega_0}, \qquad \Lambda(x) = \frac{1}{1+e^{-x}}, \tag{3}$$

where $\beta_A \geq 0$ is the sensitivity of labor's capture to AGI capability. As A_t grows with no policy offset, $\Gamma_t = 0$, the log-odds of labor capture fall and $\omega_t \to 0$: the reinstatement engine

collapses endogenously because AGI capability, rather than an assumed low rate, drives the share down. The exogenous treatment is the degenerate case $\omega_t = \omega$, a fixed constant, and $\beta_A = 0$ gives the policy-only limit in which ω_t rises with Γ_t but does not fall as capability grows.

Task allocation and closed task accounting. Each period's new tasks $\mathrm{d}N_t$ are split between labor and AI by the labor capture efficiency $e_t^{cap} = \omega_t \, \sigma_{t-1}$: labor captures $e_t^{cap} \, \mathrm{d}N_t$ and AI captures the remainder $(1 - e_t^{cap}) \, \mathrm{d}N_t$. The realized direct automation is capped by the labor tasks available, $\mathrm{d}I_t^{auto} = \min\{ \mathrm{d}I_t^{auto,g}, \, n_{t-1} + e_t^{cap} \, \mathrm{d}N_t \}$. The automated stock and labor tasks then obey

$$\mathrm{d}I_t = (1 - e_t^{cap}) \, \mathrm{d}N_t + \mathrm{d}I_t^{auto}, \qquad \mathrm{d}n_t = \mathrm{d}N_t - \mathrm{d}I_t = e_t^{cap} \, \mathrm{d}N_t - \mathrm{d}I_t^{auto}, \tag{4}$$

so the identity $n_t = N_t - I_t$ holds exactly in every period, with $n_t \geq 0$; no independent update of n_t is used. Here $\omega_t \in (0, 1)$ is the *reinstatement rate*, the share of new tasks accruing to labor, determined by equation (3) and reduced to a fixed constant only in the exogenous special case, and σ_{t-1} is the skill stock. **Key modelling choice**: the value of skills is proportional to ω_t. When $\omega_t \to 0$ as AGI takes over new-task creation, so new tasks no longer accrue to labor, skills have no economic return even at arbitrarily high levels, a monotone isolation result visualized in Figure 8. This mechanizes Restrepo's (2025) proposition that skills no longer determine wages.

Accounting scope and leakages. The closure is exact for the task, population and fiscal flows, not for a closed national-income account, and is partial-equilibrium with an exogenous supply path and an exogenous credit line. Two flows are recorded as non-recycling leakages: after-tax capital income accrues outside the modeled consumption block, and the unconsumed transfer share $(1 - \mu_{TM})TM_t$ is retained rather than spent. A third timing item is the lagged wage deduction, the difference between the tax-deducted lagged wage and the current wage staying on the firm side and leaving the tax base conservative. Absent a capital-owner recycling channel, treating these as non-returning leakages keeps the flow table complete and assumes no hidden demand; the numbers are reproduced by the leakage and wage-timing checks.

Employment and the labor share.

$$L_t^D = \bar{L} \cdot \min\{1,\ \max\{0,\ n_t/N_t\}\}, \qquad s_t = L_t^D/\bar{L}. \tag{5}$$

Skill stock (retraining vs. public employment).

$$\sigma_t = \sigma_{t-1}\Big(1 - \delta_\sigma \tfrac{U_t^{rem}}{\bar{L}}\left(1 - \rho_{ret}\,\beta_{ret}\right)\Big), \qquad \sigma_t \geq \underline{\sigma} = 0.30. \tag{6}$$

Retraining is the only instrument that actively preserves skill, with $\rho_{ret} \in [0,1]$ controlling its scale and $\beta_{ret} \in [0,1]$ how effectively it offsets decay: depreciation in equation (6) is applied only to the unemployed residual U_t^{rem}. Public employment does not actively raise skill and is not a substitute for retraining, but it preserves skill indirectly. A worker on a public job belongs to the employed share rather than to U_t^{rem}, so that worker's skill does not depreciate. Workfare therefore keeps the existing skill stock alive by keeping workers attached to a job, even though it creates no new skill and no market-valued output.

Output.

$$Y_t = (1 + g_{eff})^t\left(1 + g_{disp}\,\delta_{disp}\right), \qquad g_{eff} = g_G(1 - \eta\tau), \qquad \delta_{disp} = (I_t - I_0)/N_0, \tag{7}$$

where g_{eff} embeds the Laffer-style supply-side cost of the capital tax τ.

Capital income (tax base) and taxation.

$$\Pi_t = \max\{0,\ Y_t - w_{t-1}L_t^D\}, \qquad \text{tax}_t = \tau\,\Pi_t. \tag{8}$$

2.3. Demand side: nominal rigidity, the zero lower bound, and debt-deflation

Wage rule (empirical, not a market-clearing condition):

$$w_t = \max\{\underline{w},\ w_{t-1}\,(1 + g_W - \lambda_w\,u_t)\}, \qquad u_t = 1 - s_t. \tag{9}$$

Inflation from the consumption gap.

$$\pi_t = \max\{\pi^{lb},\ \gamma_p\,(C_{t-1}/C^{fe} - 1)\}, \qquad P_t = P_{t-1}(1 + \pi_t), \qquad C^{fe} \equiv w\,\bar{L}. \tag{10}$$

Nominal interest and the zero lower bound (ZLB).

$$i_t = \max\{0,\ r_n + \pi_t\}, \qquad r_t^d = i_t - \pi_t. \tag{11}$$

Balance-sheet-consistent household: a joint consumption–debt decision. The household makes one intertemporal choice over consumption and debt rather than choosing consumption first and accumulating residual debt. The disposable real flow in period t is

$$Y_t^d = w_t L_t^D + w^P E_t^P + \mu_{TM} TM_t - \mu_d \max\{0, r_t^d\}, \tag{12}$$

where $w^P E_t^P$ are public-employment wages and $\mu_{TM} TM_t$ are transfers subject to a leakage $\mu_{TM} \in (0, 1)$. The stock carried into the period after interest is $D_t^{roll} = D_{t-1}(1 + i_t)$. The household then chooses a single net flow, borrowing against an unfunded consumption gap at rate θ and amortizing the debt in excess of the target $\bar{b}$ at rate χ:

$$\Delta D_t^{des} = \theta \max\{0, C^{fe} - Y_t^d\} - \chi \max\{0, D_t^{roll} - \bar{b} P_t\}. \tag{13}$$

Banks supply credit against a hard underwriting ceiling b^{credit} on the debt burden, a genuine stock constraint rather than a consumption cut-off:

$$D_t = \text{clip}\Big(D_t^{roll} + \Delta D_t^{des},\, 0,\, b^{credit} P_t\Big), \qquad \Delta D_t = D_t - D_t^{roll}, \qquad b_t = D_t / P_t. \tag{14}$$

Consumption is the residual of the disposable flow and the realized net borrowing, bounded below by zero:

$$C_t = \max\{0,\, Y_t^d + \Delta D_t / P_t\}. \tag{15}$$

When the pre-truncation resources $Y_t^d + \Delta D_t / P_t$ are negative, the household cannot consume a negative amount. The uncovered portion cannot be left inside the balance sheet, so it is recorded explicitly as an external closure item

$$g_t^{unfin} = \max\{0,\, -(Y_t^d + \Delta D_t / P_t)\}, \tag{16}$$

which is interpreted as a write-down charged against the lender (default) or an externally funded relief flow. The household resource identity then closes period by period, $Y_t^d + \Delta D_t / P_t + g_t^{unfin} = C_t$, with the residual at machine precision. This item is zero on every smooth path and appears only on paths that already break the consumption floor, so it changes no smooth classification; it simply makes the accounting of a crash conservative. The consumption drag of deleveraging is identical to the real net repayment that reduces D, so no demand is suppressed by a term leaving the stock unchanged. The stock is bounded by the

bank ceiling and the flow by the zero floor with its explicit closure; debt-deflation remains active because b_t rises when P_t falls, but amortization and the credit ceiling keep D_t finite. The parameters are $\theta = 0.10$, $\chi = 0.15$, $\bar{b} = 0.35$, and $b^{credit} = 0.80$.

2.4. Fiscal closure: the transition financing gap

Policy response (with delay d):

$$\phi_t = \min\{\phi^{\max},\ \phi^{base} + \rho_{resp}\, u_{t-d}\}. \tag{17}$$

Planned spending.

$$\begin{aligned} E_t^{plan} &= w^P E_t^{P,plan} + \phi_t\, w\, U_t^{rem,plan}, \\ E_t^{P,plan} &= \min\{p_E\, u_t \bar{L},\ u_t \bar{L}\}, \qquad\qquad U_t^{rem,plan} = u_t \bar{L} - E_t^{P,plan}. \end{aligned} \tag{18}$$

Balanced budget / fiscal feasibility:

$$\text{actual spending} = \min\{E_t^{plan},\ \text{tax}_{t-1}\}, \quad \text{shortfall} \Rightarrow \text{proportional scaling } \rho = \text{tax}_{t-1}/E_t^{plan}. \tag{19}$$

The scaling factor $\rho \in (0, 1]$ applies to both components, so the financed public-job headcount and the actual unemployed remainder are

$$E_t^{P,act} = \rho\, E_t^{P,plan}, \qquad U_t^{rem} = u_t \bar{L} - E_t^{P,act}, \qquad L_t^D + E_t^{P,act} + U_t^{rem} = \bar{L}. \tag{20}$$

The remainder is therefore recomputed against the financed headcount rather than the planned one: an unfunded position does not absorb a worker, and the social pressure and skill depreciation equations below use this actual U_t^{rem}, so promised-but-unpaid jobs provide no protection. The population partition closes to machine precision in every period (verified by `analysis/verify_population_accounting.py`).

Financed-headcount residual on the corner path. The remainder is measured against the financed headcount rather than the planned one, so at $t = 5$ the actual remainder 0.186 exceeds the planned 0.137 that would ignore budget scaling, with both values from the same engine run and the partition closing to machine precision.

Appropriations in period t are funded by taxes collected in $t-1$, the government budgeting against last period's revenue with no fiscal reserve, so surpluses are not carried forward and

deficits are not rolled into debt; the fiscal account is separate from the household debt. When revenue is insufficient, spending is scaled proportionally rather than borrowed, and a financing-constraint collapse occurs when the scaled spending cannot fund the floor.

Naming the transfer. The transfer $\phi_t w U_t^{rem}$ is paid only to the unemployed remainder U_t^{rem}, is conditional on joblessness and bounded by the ceiling $\phi^{\max}$. It is therefore an unemployment transfer rather than a universal basic income: a UBI would be paid unconditionally to the whole population, including the employed, which this model does not implement. We use "unemployment transfer" (and "pure transfer" for the $p_E = 0$ limit) throughout and reserve "UBI" for the external policy literature.

2.5. Social instability (a separate failure channel)

$$\varsigma_t = \alpha_s \, (U_t^{rem}/\bar{L}). \tag{21}$$

The larger the purely-relief population (smaller p_E), the larger the social pressure. If $\varsigma_t > \varsigma^{th}$ for J consecutive periods, a *social-instability collapse* occurs. Public employment converts relief recipients into dignified jobs, reducing pressure. This is the mechanism behind "workfare $>$ pure transfer." The cutoff values $\varsigma^{th} = 0.50$, the persistence requirement $J = 10$, and the coefficient $\alpha_s = 0.60$ are reduced-form model choices rather than externally estimated quantities: ς^{th} has no direct external anchor, while α_s and J are only partially anchored (Section 5.3). The workfare-over-transfer ranking is therefore conditional on these cutoffs. Section 5 reports a systematic sensitivity sweep that quantifies how far each cutoff must move before the corner policy triggers this channel, and Section 5.3 bounds the channel against the empirical ranges.

2.6. Equilibrium and the steady state

Consumption-smooth path. Given parameters and policy $(\tau, p_E, \phi^{\max}, \omega, \dots)$, the finite-time criteria are: (i) $s_t < s^{th} \equiv 0.05$ in finite time (the employment share falls below the absorbing value); (ii) $\min_t C_t \geq C^{min} \equiv c_0 \, w\bar{L}$; (iii) inflation is not persistently negative; (iv) ς_t does not exceed the threshold persistently; (v) the financing constraint is not violated; (vi) b_t does not diverge; and (vii) the transition cannot empty the market within the early

adjustment window. Criterion (vii) is the *adjustment-speed gate*: over the early window of length $W^{early} = 10$ periods the market employment share must stay above the floor $s^{floor} = 0.50$,

$$\min_{1 \le t < W^{early}} s_t \ge s^{floor}, \tag{22}$$

which rules out an instantaneous clear-out and encodes a minimum transition time. Even if AGI can substitute labor at once, the administrative and social machinery that reassigns workers, retires positions and maintains order cannot move at the same speed, so an economy that sheds more than half its market workforce in the first few periods is recorded as a path collapse rather than a smooth transition. We call the operational classification a *consumption-smooth transition*, because criterion (iii) is not imposed as an independent veto. The two independent gates are the *fiscal gate*, criterion (ii) the consumption floor, and the *social gate*, which combines criterion (iv) the social threshold and criterion (vii) the adjustment-speed floor; (i), (v) and (vi) are enforced as stated, and the persistent-deflation criterion (iii) is measured and reported but nested inside (ii) and (vi).

Two gates, two regimes. The two gates bind in different parts of the parameter space. Under low taxation the fiscal gate is active: raising the tax rate lifts the critical automation speed from 0.005 to 0.095 at $\tau = 0.15$, and this boundary is unchanged when the adjustment-speed gate is removed, so it is a genuine financing boundary. Once the tax rate is high enough, consumption stays above the floor at every admissible speed and the fiscal gate no longer binds; the only operative constraint is then the adjustment-speed gate, producing the critical plateau near 0.14 that moves systematically with s^{floor} and W^{early}. The plateau therefore documents that a well-funded public-employment takeover is fiscally affordable, with the binding risk being the speed at which society can reassign workers rather than the budget itself.

Operational nesting rule. We report the longest run of sub-target prints and the price-level decline, so the deflation is fully visible rather than hidden, with the corner showing $J^{defl} = 79$ and the price level falling from 1.00 to 0.205. Real debt is bounded by the hard ceiling, the nominal stock contracting with the price level rather than compounding while real consumption stays above the floor. The two channels by which deflation could impose a real cost are precisely the bounded-debt condition and the floor condition, so a path satisfying

both carries no additional deflationary loss, and a spiral is recorded as collapse only when it itself breaks one of those gates. The numbers are reproduced by the deflation-nesting check. Otherwise the outcome is an economic collapse, a social-instability collapse, or not-reached, ex-post classifications over the full simulation rather than absorbing-state interruptions.

3. Main Results: Analytical Propositions

3.1. Reinstatement collapse drives the labor share monotonically to zero

Theorem 1 (Endogenous Reinstatement Collapse)**.** *Assume (A1)* $\kappa_I > 0$, $A_t = A_0(1+g_A)^t$, $A_0 > 0$, $g_A > 0$ *(a strictly monotone displacement frontier); (A2) the exogenous human-task component is bounded,* $h_t \le \overline{h} < \infty$, *and* $\sigma_{t-1} \in [\underline{\sigma}, 1]$*; (A3) the reinstatement rate follows equation* (3)*, so on the no-policy path,* $\Gamma_t = 0$*, it is* $\omega_t = \Lambda(\ell_0 - \beta_A g_t)$ *with* $g_t = \ln(A_t/A_0)$*. If for all* $t \ge t_0$*,*

$$\omega_t \, \sigma_{t-1} \, \mathrm{d}N_t < \kappa_I A_t,$$

then n_t *is strictly decreasing, there is a finite* T^* *with* $n_{T^*} = 0$*, and* $s_t = 0$ *for all* $t \ge T^*$*.*

Proof. Decompose the new-task flow into its bounded human component and the capability-driven term, $\mathrm{d}N_t = h_t + q_A A_t$. In the cap-slack region the labor-task drift is

$$\mathrm{d}n_t = \omega_t \sigma_{t-1} h_t - \Big(\kappa_I - \omega_t \sigma_{t-1} q_A\Big) A_t.$$

The first term is bounded while the second grows exponentially, with $\kappa_I - \omega_t q_A$ bounded below by the positive baseline gap, so after a finite time the second term dominates and $\mathrm{d}n_t < 0$ with a uniform negative drift. Starting from a finite initial value, n reaches the cap region in finitely many periods; once the cap binds, $\mathrm{d}n_t = -n_{t-1}$, so n reaches zero in one further step. The closed identity then keeps $n_t = 0$ thereafter. □ □

Lemma 2 (Finite-time onset of the displacement condition)**.** *Under (A1)–(A3) with* $\beta_A > 0$*, on the no-policy path there exists a finite time* t_1 *such that the premise of Theorem 1,*

$$\omega_t \sigma_{t-1} \, \mathrm{d}N_t < \kappa_I A_t,$$

holds for every $t \ge t_1$*. The premise is therefore not an additional standing assumption but a condition the model reaches in finite time from the bounded-task and exponential-growth structure.*

Proof. Using $\mathrm{d}N_t = h_t + q_A A_t$, rearrange the premise as

$$\omega_t \sigma_{t-1} h_t < \Big(\kappa_I - \omega_t \sigma_{t-1} q_A\Big) A_t.$$

By (A3), $g_t = \ln(A_t/A_0) = t\ln(1+g_A) \to \infty$, so $\omega_t = \Lambda(\ell_0 - \beta_A g_t) \to 0$. By (A2), $\sigma_{t-1} \le 1$ and $h_t \le \bar{h}$, hence $0 \le \omega_t \sigma_{t-1} h_t \le \omega_t \bar{h} \to 0$. The bracketed coefficient tends to $\kappa_I > 0$, so it exceeds $\kappa_I/2 > 0$ for all sufficiently large t, while $A_t = A_0(1+g_A)^t$ grows without bound. The right side then exceeds any finite bound as the left side converges to zero, so the inequality holds from some finite t_1 onward. In the degenerate $\beta_A = 0$ limit ω_t is a positive constant rather than a declining sequence, in which case onset is not automatic and the premise is checked directly; the lemma makes this scope explicit. □ □

Corollary 3 (Zero-reinstatement limit, $\omega_t \to 0$)**.** *Lemma 2 establishes that the premise of Theorem 1 holds for all sufficiently large t as $\omega_t \to 0$. Hence AGI capability drives the labor share monotonically to zero with* no self-correcting mechanism*: once ω_t is small enough that no new-task flow offsets displacement, nothing in the model reverses the decline.*

Remark 4. This is consistent with "skills no longer determine wages" (Restrepo, 2025), but here the reinstatement collapse is *endogenous in the rate itself*: ω_t is driven down by the capability term $\beta_A g_t$ in equation (3), rather than fixed at a low constant and left unexplained.

3.2. The deflationary spiral

Theorem 5 (Credit-Rationed Income-Flow Collapse)**.** *Assume (B1) there exist t_0 and $\varepsilon > 0$ such that, for all $t \ge t_0$,*

$$C_{t-1} \le \Big(1 + \pi^{lb}/\gamma_p - \varepsilon\Big) C^{fe} \approx 0.867\, C^{fe},$$

so that the inflation floor binds (calibrated $\pi^{lb} = -0.02, \gamma_p = 0.15$); (B2) $r_n < -\pi^{lb}$, so the ZLB gives $i_t = 0$ and $P_t = P_{t-1}(1+\pi^{lb})$ falls strictly; (B3) the bank ceiling binds persistently, $D_t = b^{credit} P_t$, because the desired net flow exceeds available credit; (B4) after the wage bill collapses the disposable flow is bounded by $Y_t^d \le \bar{Y}$, where labor income has fallen to zero and the residual transfers are limited by tax_{t-1} and the leakage μ_{TM}. Then: (i) $\pi_t = \pi^{lb} < 0$, $i_t = 0$, $r_t^d = -\pi^{lb} > 0$; (ii) the stock does not diverge: $D_t = b^{credit} P_t$ falls with P_t and $b_t = b^{credit}$

stays constant; (iii) under persistent binding the net flow contributed to consumption is

$$\Delta D_t/P_t = b^{credit}\Big(1 - 1/(1+\pi^{lb})\Big) \equiv -\delta_{lev} < 0,$$

a real deleveraging forced by the shrinking nominal credit line; (iv) $C_t = Y_t^d - \delta_{lev} \le \bar{Y} - \delta_{lev}$*, and when* $\bar{Y} - \delta_{lev} < C^{min}$ *consumption breaches the floor in finite time, triggering the economic-crash channel.*

Proof. (i) $C_t < C^{fe}$ forces the inflation floor (B1); the ZLB gives $i_t = 0$ (B2) and $r_t^d = -\pi^{lb} > 0$. (ii) The binding ceiling gives $D_t = b^{credit} P_t$; since P_t falls and $i_t = 0$, D_t falls while $b_t = D_t/P_t = b^{credit}$ is constant, so the stock is bounded rather than divergent. (iii) With the ceiling binding in both $t-1$ and t, $D_{t-1} = b^{credit} P_{t-1}$ and $D_t^{roll} = D_{t-1}$; hence $\Delta D_t = D_t - D_{t-1} = b^{credit}(P_t - P_{t-1})$ and $\Delta D_t/P_t = b^{credit}(1 - P_{t-1}/P_t) = b^{credit}(1 - 1/(1+\pi^{lb})) < 0$ because $\pi^{lb} < 0$. (iv) Substituting into the consumption identity gives $C_t = Y_t^d + \Delta D_t/P_t \le \bar{Y} - \delta_{lev}$; under B4 this lies below C^{min}, so the floor is breached in finite time. The collapse is driven by an insufficient real income flow together with credit rationing, not by an exploding debt stock. □ □

Remark 6. The two conditions cascade: Theorem 1 supplies the source of the gap (wage collapse $wL^D \to 0$), and Theorem 5 characterizes its crash dynamics (ZLB activated, transfers unable to absorb the gap, banks rationing further credit). This upgrades Fornaro–Wolf's "demand shortfall" into an explicit, decidable failure channel in which the crash follows from an insufficient real income flow rather than from an unbounded debt stock. When the floor breach in part (iv) does not occur because the financed transfer holds the real income flow at or above C^{min}, the same mechanics (i)–(iii) still operate but appear only as a falling price level and forced nominal deleveraging, with b_t constant and real consumption intact; that is the consumption-smooth path of Section 2, on which the deflation is nested rather than recorded as an independent failure.

3.3. Existence of a consumption-smooth region and the Laffer interior solution

Proposition 7 (Existence)**.** *If for all t: (C1)* $tax_{t-1} \ge E_t^{plan}$*; (C2)* $C_t \ge C^{min}$*; (C3)* $\varsigma_t \le \varsigma^{th}$*; (C4)* b_t *bounded, then* $s_t < s^{th} \equiv 0.05$ *in finite time with no crash, which defines a consumption-smooth transition under the nesting rule of Section 2. The implication is a*

definitional equivalence rather than an existence proof. Two qualifications make its scope precise. First, C1 is the full-funding condition, and no wide-grid point satisfies it strictly in every period: the count of paths with $tax_{t-1} \geq E_t^{plan}$ *at every* t *is zero. When C1 fails, spending is scaled down by the within-period rule, and a path is still consumption-smooth when the scaled spending keeps C2–C4 intact, with persistent deflation nested rather than independently vetoed. Second, under that operational criterion the corner* $(\tau = 0.15, p_E = 0.45, \phi^{\max} = 0.02)$ *and 208 of 384 wide-grid combinations are consumption-smooth in direct simulation, so the consumption-smooth region is nonempty as a verified computational fact rather than an analytically assumed one.*

Proposition 8 (Laffer interior solution τ^*)**.** *Once the labor share vanishes,* $\Pi_t \approx Y_t$*. Transition financing capacity*

$$F(\tau) = \tau\,\Pi(Y(\tau)) \approx \tau\,(1 + g_G(1 - \eta\tau))^t(1 + g_{disp}\delta_{disp})$$

is quasi-concave *in* τ*, with a unique peak*

$$\tau^R \approx \frac{1}{t\,g_G\,\eta},$$

decreasing in transition length t *and the inhibition coefficient* η*. The welfare loss* $W(\tau) = \sum_t [gap(\tau) + cost(\tau) + \delta_\tau \tau^2 tax(\tau)]$ *is strictly convex in* τ *(gap decreases concavely, deadweight increases convexly), so there is a unique interior optimum* $\tau^* \in (0, \tau^R)$*.*

Proof. Write $G(\tau) = a - b\tau$ with $a = 1 + g_G$, $b = g_G\eta > 0$, and $\Lambda \equiv 1 + g_{disp}\delta_{disp} > 0$ independent of τ, so $F(\tau) = \Lambda\,\tau\,G(\tau)^t$. Differentiating,

$$F'(\tau) = \Lambda\,G(\tau)^{t-1}\Big[a - b(t+1)\tau\Big].$$

The bracketed term is strictly decreasing and vanishes at $\tau_F = a/[b(t+1)] = (1+g_G)/[g_G\eta(t+1)] \approx 1/(tg_G\eta) = \tau^R$. Since $\Lambda G^{t-1} > 0$, $F' > 0$ below τ_F and $F' < 0$ above it, so τ_F is the unique global maximum; moreover $(\log F)'' = -1/\tau^2 - tb^2/G^2 < 0$, hence F is strictly log-concave and quasi-concave. *Numerical note.* With $g_G = 0.03, \eta = 0.40, t = 80$, the financing peak lies outside the admissible range, so τ^* is pinned by the welfare loss rather than the financing peak; direct minimization places τ^* at 0.10–0.12 across the tested ranges, always

inside the corresponding peak, and removing the decay assumption still yields an interior optimum ($\tau^* = 0.12$), so the interior result is retained, with the analytic statement conditional absent the decay. Both tests are reproduced by `analysis/check_tax_optimality.py`. For welfare, write $W = \sum_t [-B_t + C_t]$ with $B_t' \geq 0$, $B_t'' \leq 0$; we impose the local tax-base freeze used in the convexity argument, treating Π_t as locally constant in τ over a short window, so $C_t = \delta_\tau \tau^3 \Pi_t$ and $C_t''' = 6\delta_\tau \tau \Pi_t \geq 2\delta_\tau \, \text{tax}_t > 0$. Then $W'' = \sum_t [-B_t'' + C_t'''] > 0$, so W is strictly convex. We have $W'(0) = -B'(0) < 0$. The right-boundary sign $W'(\tau^R) > 0$ is imposed as an explicit decay assumption, $B_t'(\tau) \leq c\, G(\tau)^t$ for some $c > 0$, so that beyond the financing peak the marginal benefit decays while the marginal deadweight $C_t' = 3\delta_\tau \tau^2 \Pi_t$ remains non-negligible. Under this decay assumption, the intermediate value theorem gives a unique τ^* with $W'(\tau^*) = 0$, and strict convexity yields $0 < \tau^* < \tau^R$; absent the decay assumption, the interior result is conditional. □

3.4. The p_E^* interior: public employment versus transfers

Proposition 9 (Within-budget superiority of public employment)**.** *Given a tax-budget B split between EP and TM, hold the fiscal amount fixed and compare the marginal contribution to consumption of one fiscal yuan. It is $\mu_{TM} \in (0, 1)$ for transfers (leakage) and 1 for public employment. On this within-budget consumption margin public employment is strictly preferred whenever $1 > \mu_{TM}$; the claim is a marginal, fixed-budget comparison rather than a full welfare ranking, which also nets out the workfare and deadweight costs. The engine welfare ranking is reported in Table 4, including the boundary $\mu_{TM} = 1$ at which the marginal advantage vanishes and the within-budget ordering reverses once the social channel is also disabled. Shifting one unemployed worker from TM to EP:*

$$\Delta C = w^P - \mu_{TM} \phi w > 0, \qquad \Delta(\textit{fiscal}) = w^P - \phi w = w(r - \phi), \qquad \Delta\varsigma = -\alpha_s / \bar{L} < 0.$$

The direct fiscal change is positive only when $\phi < r = w^P/w = 0.85$; on an equal-outcome basis transfers cost $w^P/\mu_{TM} > w^P$ regardless. The optimal p_E^* equates the marginal gap-compression plus social-risk benefit with the marginal fiscal-plus-welfare cost. Under the explicit end-point assumptions (E0) $MB(0) > MC(0)$ and (E1) $MB(1) < MC(1)$, the loss is U-shaped in p_E and the optimum is interior and finite; otherwise it moves to the corresponding corner.

Proof. One fiscal yuan contributes 1 to consumption under public employment but only $\mu_{TM} < 1$ under transfers, and moving one worker gives $\Delta C > 0$ and $\Delta\varsigma < 0$, with the direct fiscal change positive only when $\phi < r$. For the interior, the net marginal is strictly decreasing under continuous MB and MC, so the endpoint assumptions (E0)–(E1) yield a unique p_E^* by the intermediate value theorem, with the optimum at a corner if either sign fails. At the baseline both endpoint signs are confirmed by direct simulation rather than assumed, reproduced by `analysis/check_endpoint_signs.py`. □

3.5. Social-instability threshold and the workfare channel

Proposition 10. *With $\varsigma_t = \alpha_s(1 - p_E)u_t$ (when $E_t^P = p_E u_t \bar{L} \leq u_t \bar{L}$), let u^{max} be peak unemployment. Define*

$$\alpha^*(p_E) = \frac{\varsigma^{th}}{(1 - p_E)\, u^{max}}.$$

A sufficient condition for a social-instability crash is $\alpha_s > \alpha^*(p_E)$ and *u_t remains near u^{max} for J consecutive periods, so that $\varsigma_t > \varsigma^{th}$ is sustained as in Section 2.5. A single-period peak below J does not trigger the crash even if $\alpha_s > \alpha^*$. α^* is strictly increasing and convex in p_E, and $\lim_{p_E \to 1} \alpha^* = +\infty$ (universal public employment closes the social channel). Hence raising p_E pushes the social boundary outward.*

3.6. The robustness ceiling of the buffer family

Proposition 11 (Structural ceiling $\bar{\kappa}_I$)**.** *An economic crash occurs iff some t has $C_t < C^{min}$, where*

$$C_t = Y_t^d + \Delta D_t / P_t, \qquad Y_t^d = w_t L_t^D + w^P E_t^P + \mu_{TM} TM_t - \mu_d \max\{0, r_t^d\},$$

and the net-borrowing term is bounded: it is at most θ when the ceiling does not bind, and under a binding ceiling with deflation it equals $-\delta_{lev} < 0$ so that credit cannot add to consumption (Theorem 5). Let κ_I determine the timing $t^*(\kappa_I)$ of wage collapse (Theorem 1: larger κ_I earlier) and let $\tau\Pi_t$ accumulate with $(1 + g_{eff})^t$. Assume the initial tax base is insufficient to self-finance the floor, $\tau\Pi_0 < C^{min}$. Define the critical shock

$$\bar{\kappa}_I = \inf\left\{\kappa_I : \min_{t \in [0,T]} C_t(\kappa_I) < C^{min} \text{ for all } (p_E, \phi^{\max}, \tau \leq \tau^R)\right\},$$

where $C_t(\kappa_I)$ is the model consumption under the bounded net-borrowing rule. Then (i) the buffer family protects on $\kappa_I \in (0, \bar{\kappa}_I]$; (ii) for $\kappa_I > \bar{\kappa}_I$ a crash is unavoidable for every *$(p_E, \phi^{\max})$; (iii) $\bar{\kappa}_I$ is governed by the race between tax-base accumulation and wage collapse, $A(t^*(\bar{\kappa}_I)) = \mathrm{Req}(t^*(\bar{\kappa}_I))$ with $\mathrm{Req}(t^*) = \sum_{t=0}^{t^*} E_t^{plan}$. Since buffers are finance-constrained, they can only delay a crash on a finite shock interval; strong shocks require supply-side structural measures (lowering κ_I, a reinstatement engine, steering technical direction).*

Proof. By Theorem 1, the wage collapse time is finite and moves earlier as κ_I rises; as it approaches zero, cumulative financing is limited to the insufficient initial tax base while the rationed net-borrowing term cannot add consumption, so for sufficiently large κ_I every admissible policy crashes, making the defining set nonempty and $\bar{\kappa}_I$ well defined. The upward-closure property holds because a larger κ_I accelerates displacement without changing the reinstatement engine, so a crash at one value implies a crash at every higher value; faster tax-base accumulation raises the ceiling and stronger tax inhibition lowers it. □

Remark 12 (Summary of the analytical results).

Item	Result	Key structure
P1	Reinstatement collapse $\Rightarrow s_t \to 0$, no self-correction	$\mathrm{d}n = \omega\,\mathrm{d}N\sigma - \mathrm{d}I^{auto}$, displacement dominates (Thm. 1, Cor. 3)
P2	Deflationary spiral emerges	ZLB $r_n < -\pi^{lb}$ + gap unabsorbed (Thm. 5)
P3	Smooth region exists; Laffer interior $\tau^* \in (0, \tau^R)$	$F(\tau)$ quasi-concave, W convex (Props. 7, 8)
P4	p_E^* interior (EP$\succ$TM within budget)	$1 > \mu_{TM}$; fiscal/welfare cost rises (Prop. 9)
P5	Under assumed pressure law: social threshold $\alpha^* \uparrow p_E$; $p_E \to 1$ closes channel	$\varsigma = \alpha_s(1 - p_E)u$ (Prop. 10)
P6	Buffer ceiling $\bar{\kappa}_I$; strong shocks need structure	tax-base vs wage-collapse race (Prop. 11)

4. An Analytic Bifurcation Theory: Boundary Equilibrium Bifurcation of the Reinstatement Mechanism

The switching system of Section 2 is solved numerically and its properties are stated as propositions. To make the collapse mechanism itself analytic, we now derive the fast subsystem directly from the model equations rather than postulating a normal form. Two facts follow from that derivation. First, the induced fast vector field is quadratic, not cubic: its third derivative vanishes identically. Second, the high-employment equilibrium does not meet an interior saddle-node but a *boundary equilibrium bifurcation* (BEB), at which it collides with the piecewise-smooth switching manifold created by the truncation of the human-task share and crosses it with stability preserved under the condition stated below. We then close the model by making the reinstatement rate endogenous to public employment, workfare and retraining, which makes the crossing a policy-conditioned outcome rather than an automatic one: it occurs only when the effective capture reaches the time-varying threshold derived below. As before, the reduction is a local statement; the full switching system remains the object that is calibrated, and the numerical illustration is dimensionless rather than an estimated quantity.

Two levels of bifurcation have to be kept apart, and this section treats them in order. The BEB analyzed first is a bifurcation of the fast subsystem with the slow variables frozen. Its high-employment region-I equilibrium presupposes a reinstatement rate high enough that labor keeps capturing new tasks, a state that full substitution rules out on a full path by Theorem 1; that branch is therefore a counterfactual corresponding to an economy in which full substitution is not reached, rather than a reachable endpoint. The global outcome, analyzed in the final subsection, is a different bifurcation: once market employment is driven to zero and public employment is set to absorb the entire unemployed population, the model exhibits two observed basins, the crash basin and the smooth full-absorption basin. The existence of a reduced boundary is established analytically below while the two-basin structure itself remains a numerical observation over the calibrated grid, and the boundary between them is the fiscal race between the expanding tax base and the collapsing market wage.

4.1. The fast subsystem: a quadratic vector field

Freeze the slowly evolving state and normalize the state variables $k_h = \kappa_N^h/N$, $q_A = \kappa_N^{AI} M_0$, $\mu = A/N$, $s = n/N$ and $\sigma =$ skill. In the high-employment region, where the direct automation flow binds before the availability cap and the human-task share is active, the identity $\dot{s} = \dot{n}/N - s\,\dot{N}/N$ gives the fast vector field

$$\boxed{\dot{s} = f_1(s) = -Cs^2 + Bs + A}$$

with the coefficients defined from the normalized variables and the leading nonlinearity quadratic, so no cubic coefficient on which a cusp normal form would rest is induced. The event is located not by an interior discriminant but by the boundary of the admissible state space, which is why it is a boundary equilibrium bifurcation rather than an interior fold; the normalization and full expansion are given in Appendix Appendix B.

4.2. The switching manifold and the piecewise-smooth system

The human-task share is the truncated function $S^h(s) = S_0 \max\{0, 1-\lambda_h(1-s)\}$, positive only above the switching manifold $s_{\text{floor}} = 1 - 1/\lambda_h$. For $0 \le s < s_{\text{floor}}$ the human share is identically zero and the second-region field is linear, $\dot{s} = f_2(s) = \mu(\omega\sigma q_A - \kappa_I - q_A s)$. The two fields join continuously on the manifold but their slopes differ, with the constant jump

$$f_1'(s_{\text{floor}}) - f_2'(s_{\text{floor}}) = k_h S_0\Big(\lambda_h \omega\sigma - \lambda_h + 1\Big).$$

The fast subsystem is therefore a continuous, piecewise-smooth (C^0 but not C^1) system of the standard Filippov type [13]; the manifold algebra is given in Appendix Appendix B.

4.3. Boundary equilibrium bifurcation

Theorem 13 (Boundary equilibrium bifurcation)**.** *For $\mu > 0$ and with σ fixed, a boundary equilibrium bifurcation [36, 34, 35] occurs at*

$$\boxed{\omega_c = \frac{1}{\sigma}\left(\frac{\kappa_I}{q_A} + s_{floor}\right).}$$

The crossing is transverse, $\partial_\omega f_1(s_{floor}) = \mu q_A \sigma > 0$. For $\omega < \omega_c$ the region-I root is virtual (it lies outside the physical region) and the field on the manifold points toward the absorbing boundary $s = 0$; for $\omega > \omega_c$ an interior equilibrium $s^+ > s_{floor}$ exists and is stable whenever the persistence condition $q_A\mu > C\kappa_I/q_A$ derived below holds.

The proof is given in Appendix Appendix B. The hard lower boundary contributes a second event, the region-II equilibrium entering at $\omega_0^{(\text{entry})} = \sigma^{-1}\kappa_I/q_A$, so the static picture is three regimes: absorption below the entry threshold, a stable low-employment region-II equilibrium between the thresholds, and a stable high-employment region-I equilibrium above ω_c, depicted in Figure 1.

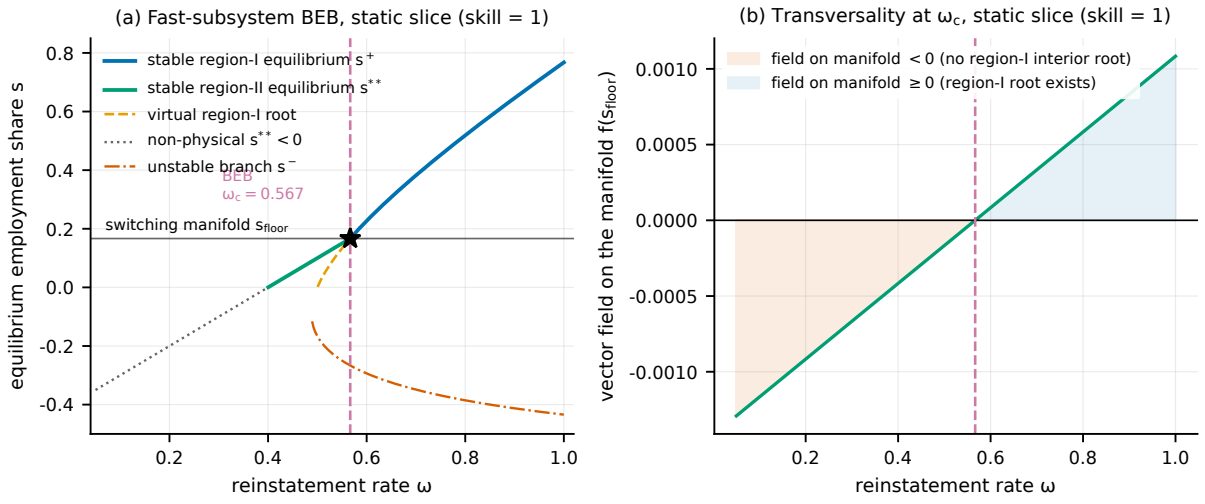

Figure 1: Boundary equilibrium bifurcation of the fast subsystem, static slice with skill fixed at one. Left: the physical equilibrium branch is absorbing at $s = 0$ for $\omega < \kappa_I/q_A$, rises as a stable region-II (low-employment) equilibrium between κ_I/q_A and ω_c, and persists through the switching manifold s_{floor} at $\omega_c = 0.567$ into the stable region-I (high-employment) branch; virtual and non-physical roots are shown light. Right: the field on the manifold $f(s_{\text{floor}})$ crosses zero transversely at ω_c. On a dynamic path skill depreciates, so the effective threshold is the time-varying $\omega_c(t)$ reported in Figure 2.

4.4. Endogenous reinstatement: capability and policy as competing log-odds

The reinstatement rate is the same endogenous variable as in the main model, equation (3), not a separate constant. Public employment, workfare and retraining reattach workers to the production of new tasks, while AGI capability erodes labor's capture. Let EP_t denote public-employment headcount and TM_t workfare and transfer spending; the policy reattachment stock is

$$\Gamma_t = \gamma_{PE}\frac{EP_{t-1}}{L^S} + \gamma_{TM}\frac{TM_{t-1}}{wL^S} + \gamma_R\,\text{retrain}\cdot\text{skill}_{t-1}, \tag{23}$$

and the reinstatement rate is the competitive logistic law

$$\boxed{\omega_t = \Lambda(\ell_0 + \Gamma_t - \beta_A g_t)\,, \quad g_t = \ln(A_t/A_0).}$$

This specification has the required properties. The logistic keeps $\omega_t \in (0,1)$ without truncation. With no policy and no capability growth it returns the baseline ω_0; capability growth, $\beta_A g_t > 0$, lowers the rate, and the policy stock Γ_t offsets that decline. Setting $\beta_A = 0$ removes the capability term and recovers the policy-only limit, while the exogenous constant $\omega_t = \omega$ is the degenerate special case used for the calibrated thresholds below.

Proposition 14 (Effective capture and the conditional crossing)**.** *The real bifurcation is governed by the effective capture $\omega_t\, skill_{t-1}$, not by ω_t alone. The instantaneous threshold on the nominal rate is*

$$\omega_c(t) = \frac{\kappa_I/q_A + s_{floor}}{skill_{t-1}},$$

which rises as skill falls. A real crossing into the high-employment region requires the effective capture to reach $\kappa_I/q_A + s_{floor}$, and is therefore conditional on skill being retained. The partial effects of the two competing terms are opposite and bounded, $\partial\omega_t/\partial\Gamma_t = \omega_t(1-\omega_t) > 0$ and $\partial\omega_t/\partial g_t = -\beta_A\omega_t(1-\omega_t) < 0$.

4.5. Dynamic verification and the critical policy intensity

The conditional crossing is verified on the full system in Figure 2, with capture peaks as full-path maxima. With no policy, effective capture never exceeds 0.052, the employment share is absorbed to zero and consumption breaks the floor ($\min C = 0.057$). Under the corner, consumption is held at 0.356 but the capture peaks at 0.121, defending consumption without restoring the labor engine. Under the strong floor, retraining retains skill (σ ends at 0.96), the capture crosses at $t = 35$ and employment is retained with $\min C = 0.447$, a mid-horizon crossing whose durability is qualified by the β_A sweep; at the weaker strength the capture peaks at 0.498, still below the threshold, so the crossing is conditional on the public-employment intensity.

A bisection on the public-employment intensity gives the sharp threshold at which consumption is defended, defined as $\min_t C_t \geq C_{\min}$:

$$p_E^* = 0.3661,$$

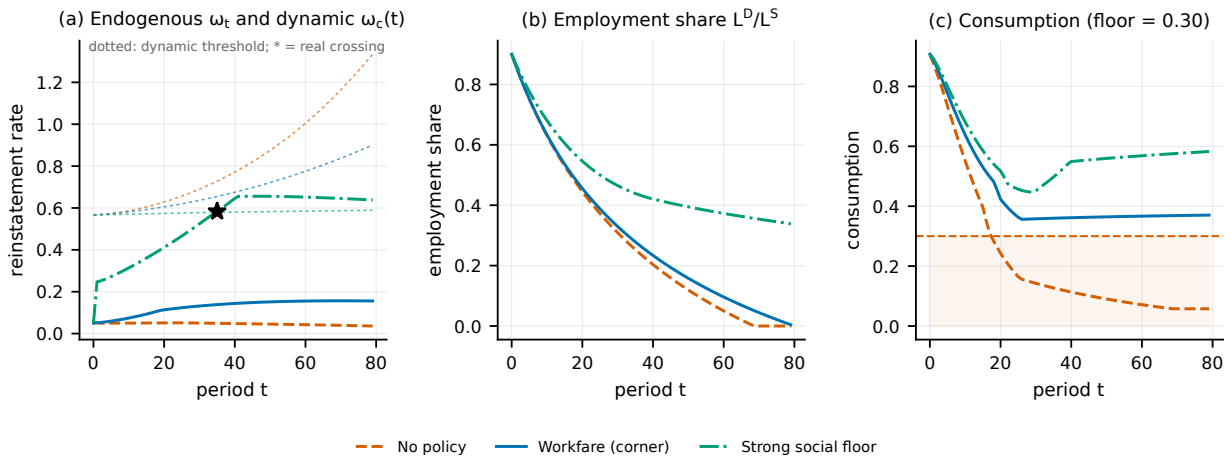

Figure 2: Endogenous reinstatement and the resulting dynamic paths. (a) The endogenous rate ω_t (solid) against its instantaneous dynamic threshold $\omega_c(t)$ (dotted); the strong floor at $p_E = 0.80$ crosses at $t = 35$ under the baseline $\beta_A = 1$ (marked $*$), while the corner and no policy stay below their thresholds. (b) Employment share and (c) consumption; the strong floor retains employment and the highest consumption, the corner holds consumption near the 0.30 floor as market employment vanishes, and the no-policy path collapses.

below which the economy crashes and above which consumption is held at its floor. This is a model-implied consumption threshold, not an identified estimate or a high-employment threshold: at p_E^* the effective capture does not reach the critical value, so consumption is defended by the fiscal buffer without restoring market employment. The long-horizon run confirms the distinction, with the strong-floor employment share retained at a positive but still-declining level (s_L ends at 0.17) rather than settling.

4.6. Multiple time scales and the finite-rate lag in discrete time

The calibrated model is a discrete-time recursion, not a continuous flow, so we state the time-scale separation without introducing an undefined continuous parameter. Within each period the endogenous rate is updated first from the previous policy stock and then the employment share is updated from the task accounts. The logistic form compresses the rate near its bounds, so on paths with a weak policy response the rate moves little per period while employment reacts directly: on the corner path the mean absolute change of s_L is about 8.4 times that of ω, a clear separation, and the employment share tracks a target set by the current rate with a one-period relaxation lag. The separation is not universal, since on the

strong-floor path the two mean changes are comparable, so it is reported as a path-dependent numerical property rather than assumed. Geometric singular perturbation theory is used here only as the conceptual lens for this finite-rate lag and the piecewise-smooth persistence structure; the continuous-time Fenichel results are not asserted as theorems of the discrete recursion, whose actual behavior is the object simulated. The static interior equilibrium of Theorem 13 is not by itself an attractor of the full model. On a full path the verified signature of an effective crossing is a discontinuous flattening of the market-share slope, not a reversal or interior convergence: in the strong regime the mean per-period decline of s_L falls from about -0.009 to about -0.003 while remaining strictly negative, and s_L never increases. The discrete update order and the lag accounting are given in Appendix Appendix B.

4.7. Connection to the calibrated model

The high-employment equilibrium corresponds structurally to the strong social floor, the workfare corner to the fiscally defended state as market employment vanishes, and the absorbing regime to the no-policy and pure-transfer collapses. The coefficients $\gamma_{PE}, \gamma_{TM}, \gamma_R$, the baseline ω_0 and the capability sensitivity β_A are structural rather than externally estimated, and the threshold $p_E^* = 0.3661$ is a dimensionless output of the calibrated model, illustrative rather than an empirical estimate. On the corner path the region-I slope stays strictly negative, so the persistence-type classification is supported by the calibrated parameters.

The probit comparison of the share law, the $\beta_A \in \{0, 1, 3\}$ capability sweep and the counterfactual that removes the logistic erosion term are extended robustness runs rather than main-line results; they are reported in full in Online Appendix D, with the probit and counterfactual reproduced by `analysis/check_link_function.py` and `analysis/check_capability_counterfactual.py`.

4.8. Global outcome bifurcation: crash versus full public-employment absorption

Under full substitution, set the public-employment policy to full absorption, the planned headcount equal to the entire unemployed population so the target share rises to one as market employment falls, while the within-period fiscal constraint is unchanged and unfunded headcount remains residual unemployment. Two outcomes follow: if the tax base expands fast enough, public employment grows in step with the released workers, residual unemployment

ends at zero and the path is smooth, while if the fiscal base lags, unfunded workers accumulate and consumption breaks the floor, giving the crash basin. The boundary is the fiscal race of Proposition 11, decided by whether the accumulating capital-income tax base or the collapsing wage bill leads.

Before reporting the numerical boundary, the reduced analytic core guarantees that one exists.

Proposition 15 (Existence and uniqueness of the reduced critical frontier)**.** *Fix the capital tax and all slow parameters and reduce the system to its one-dimensional fiscal-feasibility core, defining the minimum consumption buffer over the path*

$$B(g_A) = \min_{t\in[0,T]} \Big(C_t(g_A) - C^{min} \Big).$$

Assume on this reduced core: (R1) the path depends continuously on g_A; (R2) the feasibility classification is monotone, so once a speed crashes every larger speed crashes and the smooth set is an interval; (R3) the zero-speed path is smooth and some finite speed crashes. Then there is a unique critical value $g_A^* > 0$ separating the two sets: every $g_A < g_A^*$ is smooth and every $g_A > g_A^*$ crashes. The monotonicity in (R2) is framed at the level of the classification rather than the pointwise buffer, because the buffer itself need not be strictly monotone. On a fine grid with step 0.001*, the minimum consumption shows small local reversals, with at most* 65 *upward steps per tax rate and a largest reversal of* 0.0023*, yet the smooth-versus-crash classification crosses exactly once over the whole interval for every tax rate, which is the numerical content of (R2); the proposition supplies the conditional analytic conclusion under that assumption.*

Proof. By (R1) and (R3), the smooth set contains the origin and is bounded above, and by (R2) it is an interval, so its boundary is a single critical value g_A^*; the classification places slower growth in the smooth region and faster growth in the crash region. On the analytic core, continuity follows from continuous dependence of the difference-equation path on its parameter. The proof does not require the pointwise buffer to decrease at every step, only that the crash set be upward closed, which is weaker and matches the fine-grid evidence of a single crossing despite small local reversals in the buffer. The bisection below does not

establish existence; it locates the g_A^* whose existence is proved here. This is a one-dimensional reduction with slow variables frozen, not a claim that the full high-dimensional switching system has only two attractors, which remains a numerical observation over the calibrated grid. □ □

Consistent with Proposition 15, a bisection on the frontier growth locates the boundary. Under $\tau = 0.15$ the critical value is $g_A = 0.095$, located at the consumption floor: grid points at $g_A = 0.07$ remain smooth with $\min C = 0.326$, whereas $g_A = 0.10$ crashes with $\min C = 0.295$. The boundary moves with the capital tax, from $g_A = 0.016$ at $\tau = 0.10$, through 0.095 at $\tau = 0.15$, to 0.138 at $\tau = 0.20$, after which it stays near $g_A = 0.14$. This plateau is not a Laffer effect. Removing the adjustment-speed gate while holding every other rule fixed leaves the low-tax boundary unchanged at each tax rate, but the boundary for $\tau \geq 0.20$ then moves beyond the search upper bound 0.25: consumption stays above the floor at every admissible speed and no fiscal crash occurs. The plateau is therefore set by the adjustment-speed gate, not by taxation slowing the tax base, and it indicates that a well-funded public-employment takeover is fiscally affordable, with the operative limit being the speed of worker reassignment. Figure 3 maps the two basins over the (τ, g_A) plane with the two gates distinguished, and Figure 4 reports the smooth reallocation: market employment falls as public employment rises, residual unemployment returns to zero, and consumption stays above the floor throughout.

The boundary is not an artifact of removing transfers. Two comparisons establish this. First, when the unfunded residual is allowed a transfer payment from the fiscal room left after public employment, the critical frontier speed under $\tau = 0.15$ is unchanged at $g_A = 0.095$; under the workfare-first allocation order this residual room is essentially zero, with the realized transfer at 10^{-16}, so that particular switch does not run a positive-spending transfer and cannot by itself identify the transfer effect. Second, a same-budget allocation that reserves a fixed share of each period's tax revenue for transfers produces a genuine positive transfer flow, and on that comparison shifting budget from public employment to transfers lowers the minimum consumption at every step, from 0.295 at zero transfer share to 0.000 at the pure-transfer limit near the boundary, and contracts the critical frontier monotonically, from 0.095 to 0.005 at $\tau = 0.15$. The workfare ranking therefore survives a comparison in

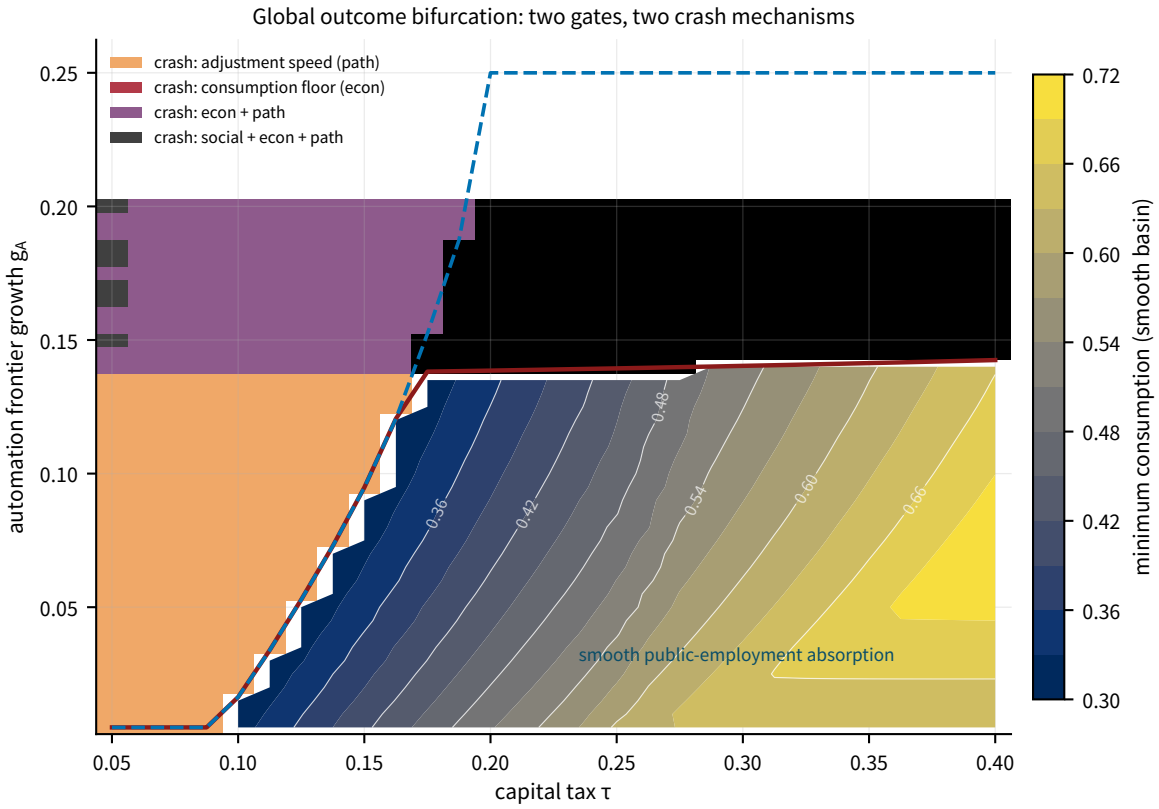

Figure 3: Global outcome bifurcation under full absorption. The colored region is the smooth public-employment basin, with the color giving the minimum consumption; the crash basin is split by mechanism, with the fiscal-gate boundary (consumption floor) and the adjustment-speed boundary (early-window employment floor) drawn separately. Up to $\tau \approx 0.15$ the operative boundary is the fiscal gate and rises with the tax rate to $g_A = 0.095$; for $\tau \geq 0.20$ consumption stays above the floor at every admissible speed and the operative boundary is the adjustment-speed gate near $g_A = 0.14$. The plateau therefore reflects the minimum transition time rather than a Laffer trade-off. Keeping a transfer buffer for the unfunded residual does not move the boundary.

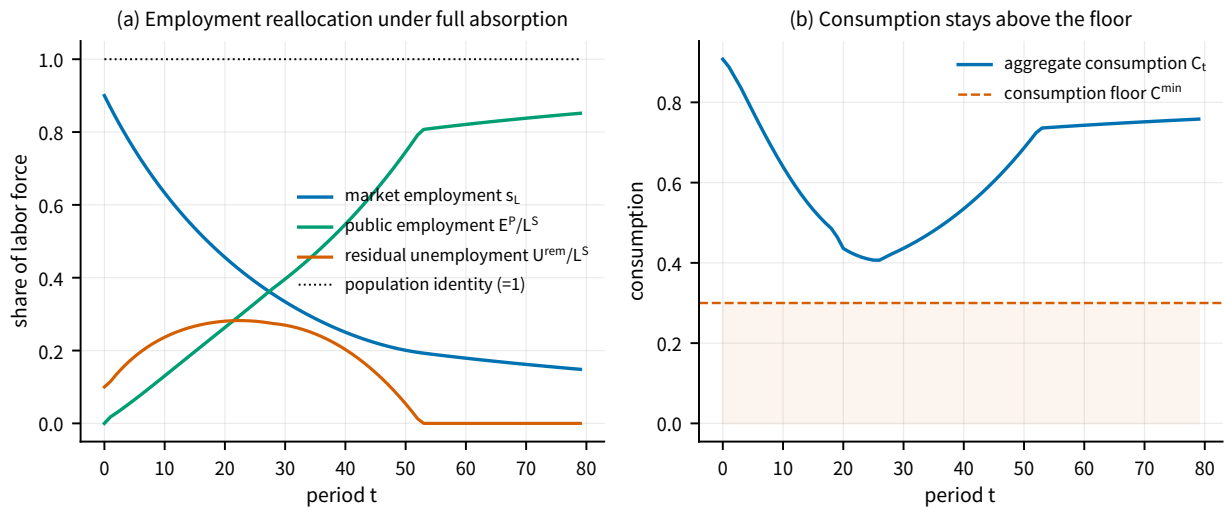

Figure 4: Smooth full-absorption path at $g_A = 0.010$, $\tau = 0.15$. Left: market employment declines as public employment rises to absorb the released workers, residual unemployment first rises in the fiscally tight phase and then returns to zero, and the population identity stays at one. Right: consumption dips in the tight phase but remains above the floor and recovers as the tax base expands.

which transfers actually spend money: a public job carries a unit consumption coefficient and rebuilds the social channel, whereas a transfer leaks through $\mu_{TM} < 1$ and does neither. The global bifurcation rests on the fiscal race and the allocation order rather than on the pure-public-employment specification, and the entire set of numbers in this subsection is reproduced by `analysis/check_full_absorption.py` together with the same-budget transfer check.

5. Calibration

5.1. Parameter–data mapping

Standardization $L^S = \bar{L} = 1$, $w = 1$. The reinstatement rate is held at its exogenous special case $\omega = 0.05$ in this section, while the main model endogenizes it and reports its own threshold, the two reconciled in Section 4.7. Lowering the transfer ceiling to $\phi^{\max} = 0.001$ at the corner lowers $\min_t C_t$ from 0.357 to 0.353, so the 0.003 gap is the buffer carried by a two-percent transfer ceiling.

What "calibration" means here. Three entries are anchored to data: the consumption floor ratio c_0 to the U.S. absolute poverty line, the transfer MPC μ_{TM} to total-consumption

MPC estimates for low-liquidity recipients, not the in-kind SNAP margin, and the workfare wage ratio w^P/w to workfare programmes. One group sits in a literature range on an annual-frequency convention: the model period is one year, so a quarterly Calvo no-reset probability $\zeta_q = 0.75$ maps to $\zeta_y = \zeta_q^4 = 0.316$, a mean annual duration of 1.46 years, and the slopes γ_p, λ_w are annual-rate reduced-form conventions. The remaining entries are model-set, among which κ_I is a calibration target set so the $T = 80$ horizon reaches $s_t \to 0$, not an estimated displacement rate, so the completion within 80 periods restates the target rather than tests it. The social and accounting coefficients are conventions as well. Calibrated therefore means three data-anchored magnitudes plus a two-parameter literature range, with everything else declared as setting; the parameter vector has not been estimated.

Param	Meaning	Baseline	Anchor / source
$s_0 = (N_0 - I_0)/N_0$	initial labor share	0.90	model initial state $I_0 = 0.20$, $N_0 = 2.00$ gives $s_0 = 0.90$; U.S. labor share 53.8% is a benchmark only *[model initial state; see note]*
κ_I	automation displacement	0.020	transition (T=80) drives $s_t \to 0$ *[calibration target; set to hit $s_t \to 0$ at T=80; not estimated]*
g_A	automation frontier growth	0.010	long-run U.S. TFP $\approx 1\%$/yr; the compute-cost decline is not used [46] *[model-set; see note]*
η	capital-tax growth inhibition	0.40	no direct anchor; a growth-inhibition coefficient, not a tax rate [14, 26] *[model-set; see note]*
γ_p, λ_w	nominal rigidity	0.15, 0.12	Smets–Wouters Calvo $\zeta_p = \zeta_w = 0.75$ (Nakamura–Steinsson; Bils–Klenow) [30, 25, 8]; quarterly $\zeta_q = 0.75 \to \zeta_y = \zeta_q^4 = 0.316$ annual, mean duration 1.46 years, and the two slopes are annual-rate reduced-form conventions *[literature range, annual frequency]*

Param	Meaning	Baseline	Anchor / source
μ_{TM}	transfer MPC (total consumption)	0.50	total-consumption MPC out of transfers: Karger–Rajan EIP 0.46; CARES low-liquidity 0.53–0.66; Cooper–Olivei; IMF 0.20; Miller 0.44–0.55 [11, 12, 18]. The USDA SNAP value 0.30 is the *food-at-home* MPC (the other 0.70 is reallocated across goods, not lost to saving), so it is a different margin and is not used to anchor this total-consumption coefficient [10] *[literature range, total-consumption MPC]*
c_0	consumption floor ratio	0.30	U.S. absolute poverty threshold (ASPE/HHS), divided by the baseline full-time wage income $wL^S = 1$ to give the normalized floor; the historical "food $\times 3$" origin is noted but is not the normalization used here *[data-anchored level; normalization explicit]*
ω	reinstatement rate	0.05	A&R: reinstatement weaker than displacement [2] *[model-set; direction grounded, magnitude not estimated]*
w^P/w	workfare wage ratio	0.85	MGNREGA / World Bank workfare wages set below the market wage (direction grounded); the specific 0.85 ratio is a model setting rather than a point estimate [32] *[direction data-grounded; level model-set]*

Note. The initial share $s_0 = 0.90$ is computed from the task block as an internal consistency requirement, with the U.S. labor income share serving only as a qualitative benchmark since s is a task share and enters no equation. The frontier growth is set at the long-run TFP rate; the hardware-cost decline and efficiency gain reported by Stanford HAI and NVIDIA refer to the cost of computing rather than A_t and are not used as an anchor. The coefficient η scales the growth cost of the tax and is not an effective tax rate, so EATR levels and tax-base elasticities serve as magnitudes only. The symbol σ_t denotes the skill stock, not a capital–labor elasticity, and the model has no CES production block; the broader elasticity ranges in task-based calibrations are background only.

Param	Meaning	Baseline	Anchor / source
α_s	social-pressure coefficient	0.60	$\varsigma_t = \alpha_s U_t^{rem}/\bar{L}$; relief share drives instability *[model-set / calibration convention]*
ς^{th}	social-instability threshold	0.50	sustained $J = 10$-period exceedance $\Rightarrow$ social collapse *[model-set / calibration convention]*
T	simulation horizon	80	transition window over which $s_t \to 0$ is computed *[model-set / calibration convention]*
δ_σ	skill depreciation	0.015	skill stock decay per period unemployed *[model-set / calibration convention]*
g_{disp}	automation output boost	0.05	$\delta_{disp} = (I_t - I_0)/N_0$ output dividend *[model-set / calibration convention]*
θ	borrowing response to gap	0.10	$\theta \max\{0, C^{fe} - Y_t^d\}$ new-borrowing term in the net-flow decision *[model-set / calibration convention]*
χ	amortization of excess debt	0.15	$\chi \max\{0, D_t^{roll} - \bar{b}P_t\}$ net deleveraging rate *[model-set / calibration convention]*
b^{credit}	bank credit ceiling	0.80	hard underwriting bound $D_t \leq b^{credit} P_t$ on the debt burden; a stock constraint, not a consumption cut *[model-set / calibration convention]*
μ_d	monetary drag on disposable flow	0.06	$-\mu_d \max\{0, r_t^d\}$ *[model-set / calibration convention]*
$\bar{b}$	debt burden target	0.35	target real debt in the amortization rule *[model-set / calibration convention]*
D_0	initial nominal debt (normalized)	0.30	initial balance sheet *[model-set / calibration convention]*
s^{floor}	early-window employment floor	0.50	adjustment-speed gate: $\min_{t<W^{early}} s_t \geq s^{floor}$, a minimum transition time that rules out an instantaneous clear-out *[model-set; social gate]*
W^{early}	early adjustment window	10	length over which the employment floor binds; aligned with the later statistics window *[model-set; social gate]*

Param	Meaning	Baseline	Anchor / source
s^{TM}	transfer budget share (same-budget check)	0.00	share of each period's tax reserved for transfers in the positive-spending comparison; 0 is the workfare-first baseline, $(0, 1]$ runs a real transfer flow *[model-set; diagnostic]*
g^{unfin}	unfinanced closure at zero truncation	0.00	write-down or external relief that closes the household identity when pre-truncation resources are negative; zero on every smooth path, nonzero only on a crash already breaking the floor *[accounting closure]*

Baseline policy levers (headline corner). $\tau = 0.15$, $p_E = 0.45$ (workfare-dominant), $\phi^{\max} = 0.02$ (the grid floor; transfers effectively closed under the baseline loss weights). This is the reported headline, which retains a buffer; the grid's mathematical minimum under the baseline weights sits at $(\tau, p_E) = (0.10, 0.40)$, as explained below.

The transition-loss objective. The grid search ranks policies by a single scalar, and we therefore state that scalar explicitly instead of leaving it implicit in the simulation code. Writing $C^{fe} = w\bar{L}$ for full-employment consumption, the objective for a policy path $(\tau, p_E, \phi^{\max})$ is

$$\mathcal{L}(\tau, p_E, \phi^{\max}) = \sum_{t=0}^{T} \Big[\max(0, C^{fe} - C_t) + \lambda\, TM_t + \lambda_{PE}\, w^P EP_t + \nu\, EP_t^2 + \delta_\tau\, \tau^2 \mathrm{tax}_t \Big], \tag{24}$$

with $\lambda = 0.5$, $\lambda_{PE} = 0.6$, $\nu = 0.5$ and $\delta_\tau = 0.6$. The four terms are in consumption units: the consumption gap, transfer outlays charged at the leakage rate, public-employment outlays with a congestion term, and the quadratic tax deadweight that produces the Laffer trade-off. Feasibility is a separate criterion and is not part of $\mathcal{L}$: a path is admissible if it satisfies the consumption floor in both windows, $C_t \geq C_{\min} = c_0\, w\bar{L}$ for $t \geq 10$ and separately for $1 \leq t < 10$ so an early transient cannot hide a breach, and additionally passes the adjustment-speed gate $\min_{t<10} s_t \geq s^{floor} = 0.50$. The quoted statistic $\min_t C_t$ in the calibration subsections and in Figure 5 uses the $t \geq 10$ window for comparability with earlier tables, while the classification uses both windows together with the speed gate. Proposition 8 is the one-dimensional projection of (24): with p_E and $\phi^{\max}$ held fixed, the transfer and workfare charges collapse into its single $cost(\tau)$ term and the deadweight enters with the same quadratic form, so $W(\tau)$ and $\mathcal{L}$ rank policies identically along the τ axis. The four weights are conventions rather than estimates, so $\mathcal{L}$ is a scenario loss index under stated weights rather than a normative welfare measure, with no household utility specified; the normative statements are confined to feasibility and financing, and the loss numbers are comparative scenario statistics. Throughout the calibration, reported path statistics on the unit scale (consumption, stress, headcount and share values) are rounded

to three decimals, while aggregate loss and fiscal totals are rounded to two; the sharp bisection thresholds that locate a boundary are kept to four decimals. Declared parameters and policy levers retain their setting precision and are not rounded outputs.

External ranges for the two policy instruments. Two empirical ranges check the settings without becoming inputs. For workfare, Lee, Ko and Kim [41] estimate that one public-sector position raises private employment by one, and Gechert [40] reports public-spending multipliers near one that exceed those of transfers; the model omits the private-employment multiplier, so adding it would raise the workfare ranking. For the pure transfer, Vivalt et al. [42] find a small labor-supply reduction from a guaranteed income; the model has no hours margin and holds labor supply fixed, which flatters the transfer by leaving the tax base unshrunk. Both gaps therefore run in the direction that makes the ranking harder to establish, and neither range enters an equation; this is the sense in which the policy claims are model-implied rather than universal.

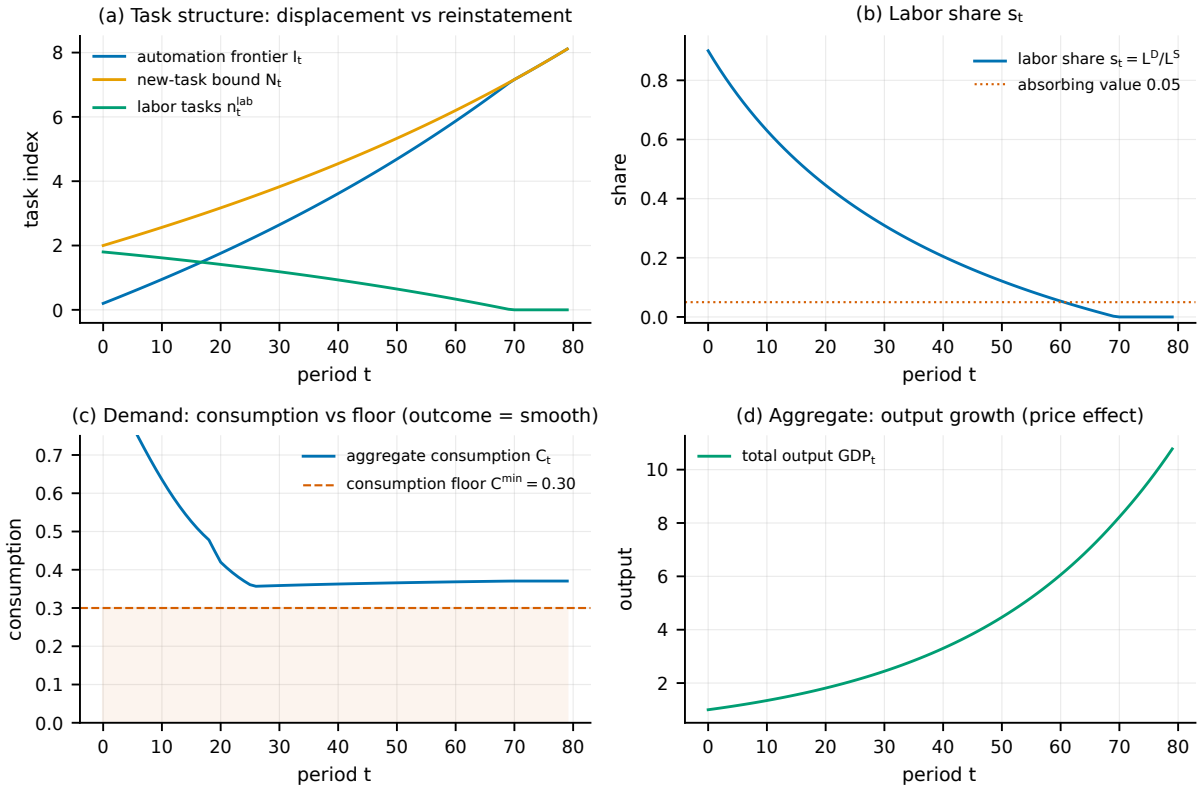

Figure 5: Baseline smooth transition under the corner configuration ($\tau = 0.15, p_E = 0.45, \phi^{\max} = 0.02$) at the baseline frontier growth $g_A = 0.010$. (a) The new-task bound N_t initially exceeds the automation frontier I_t and both grow, with the frontier catching up near the horizon while labor tasks n_t^{lab} fall to zero. (b) The labor share declines monotonically to its absorbing value. (c) Aggregate consumption stays above the floor $C^{min} = 0.30$ (minimum 0.357). (d) Total output keeps rising through the transition.

5.2. Robustness of the analytical results under the calibrated parameters

Figure 5 reports the baseline path under the corner configuration. Under the calibrated parameters ($\mu_{TM} = 0.50$, $\eta = 0.40$), transfers are costly relative to public-employment wages and the capital tax carries a Laffer supply-side cost. Running the full battery under the calibrated engine with the reinstatement rate held at its exogenous special case $\omega = 0.05$, exactly as in the named check scripts, yields the following calibrated outcomes:

Result	Calibrated outcome	Conclusion
Policy delay d	corner ($\phi^{\max}$=0.02): d=0 and d=12 both smooth (0.357); standard ($\phi^{\max}$=0.65): d=0 and d=12 both smooth (0.358 and 0.366)	delay immaterial at the corner and under the standard setting
Isolation gain Δ vs ω	$0.018 \to 0.514$	monotone, robust
Workfare vs pure transfer	6/6 not crashed (4 smooth/reached, 2 not-reached) vs 6/6 crashed	workfare > transfer at every ω
Minimum-loss point (grid)	$(0.10, 0.40, 0.02)$	corner: workfare-dominant, close transfers, low tax
Feasible share, p_E=0.45 vs 0.30	64.1% vs 26.6%	advantage retained
No-policy / pure-transfer	crash / all crash	buffering and financing necessary

The feasible share is the fraction of grid cells smooth under the operational criterion in Proposition 7: $41/64 = 64.1\%$ at $p_E = 0.45$, $17/64 = 26.6\%$ at $p_E = 0.30$, and $208/384 = 54.2\%$ overall. The workfare–transfer row is a same-fiscal comparison on identical $(\tau, \phi^{\max})$: across six ω values workfare survives all six (four reach the target and two are not-reached, so the count is not a claim that all six reach it) while the pure transfer crashes all six. The ranking rests on declared social-instability parameters with no external identification; their anchoring and the region where even the workfare corner fails are documented in Online Appendix C.

Engine convention for the corner minimum. The corner minimum consumption is reported as 0.357 in this calibration, where the reinstatement rate is fixed at $\omega = 0.05$; under the endogenously evolving reinstatement

rate used in the bifurcation analysis, the same corner gives 0.356. The difference is below 0.001 and reflects only whether ω is held fixed or allowed to move with policy, with no effect on any ranking or conclusion.

The public-employment intensity is load-bearing. The same six ω values survive at $p_E = 0.45$ but all collapse at $p_E = 0.30$, every path through the floor; the corner survives only above a share of about 0.36, a feasibility bound rather than a tuning preference.

Table 3: Structural decomposition of the pure-transfer failure. All four runs use the identical fiscal setting ($\tau = 0.16, p_E = 0, \phi^{\max} = 0.65$) and vary only the two structural choices the workfare corner does not share: the transfer consumption MPC μ_{TM} and the social-instability coefficient α_s. Reproduced by `analysis/check_transfer_structure.py`.

Configuration	outcome	crash type	$\min C$
Baseline ($\mu_{TM} = 0.50, \alpha_s = 0.60$)	crash	both	0.259
Equal MPC ($\mu_{TM} = 1.00$)	crash	social only	0.409
Social disabled ($\alpha_s = 0$)	crash	economic	0.259
Both relaxed ($\mu_{TM} = 1.00, \alpha_s = 0$)	smooth	none	0.409

The decomposition separates the two mechanisms as detailed in the table: an equal MPC leaves only the social channel, while disabling the social channel but retaining MPC leakage still leaves an economic crash, and the regime is smooth only when both are relaxed. The workfare advantage therefore rests on the unit workfare MPC together with the relief-to-jobs conversion rather than a generic financing failure, with the time paths in Figure 6.

Table 4: Symmetric-limit welfare comparison on the same fiscal setting ($\tau = 0.16, \phi^{\max} = 0.65$), with the transfer MPC set to one and the social channel disabled ($\mu_{TM} = 1, \alpha_s = 0$). The two columns differ only in the public-employment share p_E. Total loss is the engine welfare loss and fiscal spend is the transfer plus workfare wage bill. Reproduced by `analysis/check_symmetric_welfare.py`.

Regime	outcome	total loss	fiscal spend	$\min C$
Public employment ($p_E = 0.45$)	smooth	55.34	36.12	0.418
Pure transfer ($p_E = 0$)	smooth	51.23	32.01	0.409

The symmetric limit reverses both the feasibility classification and the welfare ranking, the pure transfer attaining a lower total loss at a lower spend as reported in the table. Once the transfer MPC equals one and the social channel is disabled, a transfer yuan supports consumption as a workfare wage does, while the

public-employment path still carries its workfare cost, which then dominates. The reversal is a conditional result requiring both $\mu_{TM} = 1$ and $\alpha_s = 0$ simultaneously, and the calibrated values satisfy neither; these numbers are the boundary at which the ranking changes, not the baseline case.

Same-budget allocation across outcome dimensions. The symmetric limit above is a boundary case. Three further computational experiments, reproduced by `analysis/check_fiscal_mu_margin.py`, `analysis/check_fiscal_allocation_multi.py` and `analysis/check_fiscal_allocation_mc.py`, examine the calibrated interior rather than that boundary. First, holding the fiscal amount fixed and sweeping the transfer MPC over $\mu_{TM} \in [0.30, 0.99]$, the public-employment consumption floor is at least the transfer floor at every $\mu_{TM} < 1$ in all five scenarios, and no numerical reversal appears below $\mu_{TM} = 0.999$, consistent with the analytic flip at $\mu_{TM} = 1$. Second, sweeping the within-budget transfer share from zero to one, the consumption floor, peak social stress, residual unemployment and unfinanced gap all move monotonically against the transfer regime, whereas the engine total welfare loss is lower under pure transfers in four of the five scenarios because that loss books the workfare wage and its quadratic cost but does not treat the breached floor and social threshold as infeasible. Under the calibrated parameters the pure-transfer path crashes in all five scenarios while the public-employment corner is smooth in three, so the lower transfer loss is recorded on infeasible paths. Third, a Monte Carlo over 400 draws of $(\mu_{TM}, \alpha_s, \phi^{\max})$ finds public employment smooth while transfers crash in 100% of draws, with a Clopper–Pearson 95% interval of $[0.991, 1]$, and no draw in which both are feasible. The evidence separates a feasibility claim from a cost claim: public employment is the instrument that satisfies the floor and social constraints, while transfers carry a lower booked welfare cost only on paths that violate those constraints, or under the symmetric-limit assumptions the calibration does not meet.

The rationing order under a constrained budget. The preceding experiments rank the two instruments but do not state the order in which a budget that cannot cover full absorption should be released. A fourth computational experiment, reproduced by `analysis/check_fiscal_rationing_order.py`, raises the available budget from zero to full coverage and allocates it under two rules: the engine's public-employment-first rule, which hires as many workers as the budget allows and spends the residual fiscal room on transfers to the remaining unemployed, and a counterfactual transfer-first rule. On the constrained interval, where the budget is at or below the cost of full public-employment coverage, the first positive budget funds a public job and the employment-first rule delivers at least as much consumption at every budget level in all five parameter settings. The mean advantage shrinks as the transfer MPC rises, from 0.063 at $\mu_{TM} = 0.50$ to approximately zero at $\mu_{TM} = 0.99$, because a public-employment yuan enters consumption at one whereas a transfer yuan enters at μ_{TM}, and the two coincide only as μ_{TM} approaches one. This is a numerical observation of the within-budget order, not an analytic ranking: the budget should first secure public employment, and transfers are funded from the residual room. Only once the budget exceeds the full-coverage cost, so that the constraint no longer binds, can the transfer-first sequence fund both instruments simultaneously and record a marginally higher consumption, a surplus case rather than a rationing one.

Sensitivity to g_A and η. Sweeping g_A over $\{0.010, 0.05, 0.10, 0.20, 0.30\}$ gives minimum consumption $0.357, 0.344, 0.294, 0.237, 0.222$ with outcomes smooth, smooth, crash, crash, crash; the buffer holds at $g_A = 0.05$, one sixth of the often quoted hardware-cost decline, and the floor is breached at 0.10. As the sharpest calibration sensitivity, the smooth conclusion is conditional on a conservative long-run-TFP frontier rate rather than a hardware-cost rate. By contrast η is nearly inert, every corner outcome smooth at $\min_t C_t = 0.357$ with the total loss moving about 0.1%, so its imprecision affects no conclusion and no sharp Laffer effect can be claimed at $\tau = 0.15$.

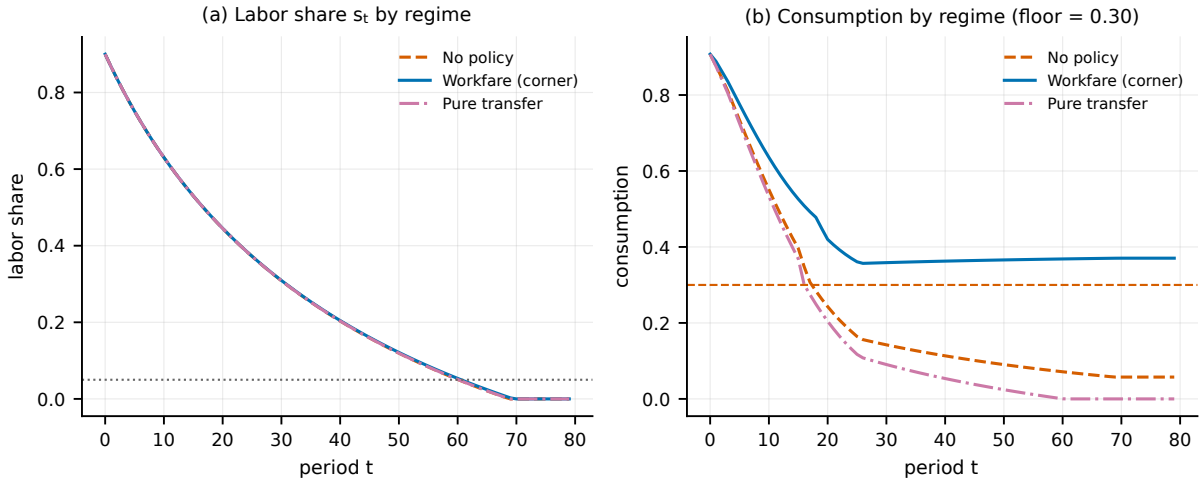

Figure 6: Policy-regime comparison. Each regime carries its own fiscal setting: no policy ($\tau = 0.05, \phi^{\max} = 0.15$), the workfare corner ($\tau = 0.15, p_E = 0.45, \phi^{\max} = 0.02$), and the pure transfer ($\tau = 0, \phi^{\max} = 0.65$). This is therefore a comparison of regimes rather than a same-fiscal instrument test, which is given in the table above. (a) The labor share s_t follows the same task-driven decline under all three regimes. (b) The workfare corner holds aggregate consumption above the floor, whereas the no-policy and pure-transfer regimes fall below it and become infeasible; the consumption buffer, not the market employment count, is what distinguishes the regimes.

Grid minima and identification. Figure 7 visualizes the loss surface, whose minimum is at $(0.10, 0.40)$ with the loss locally flat and the coordinates grid-dependent rather than sharply identified. The minimum clears the floor by only a few thousandths, so we report the better-buffered corner $(0.15, 0.45, 0.02)$ with $\min_t C_t = 0.357$ as the headline, a deliberately conservative choice. Lowering $\phi^{\max}$ lowers the loss monotonically, so closing transfers is a preference of the objective rather than a grid artifact.

Sensitivity to the loss weights. Feasibility is weight-independent: re-ranking all grid points under six weight configurations leaves the admissible set at 208 points in every case, while the ranking among admissible paths depends on them. The minimizer moves across configurations, yet public employment remains the dominant instrument in every case ($p_E \in [0.30, 0.55]$), whereas the transfer ceiling varies widely. Workfare

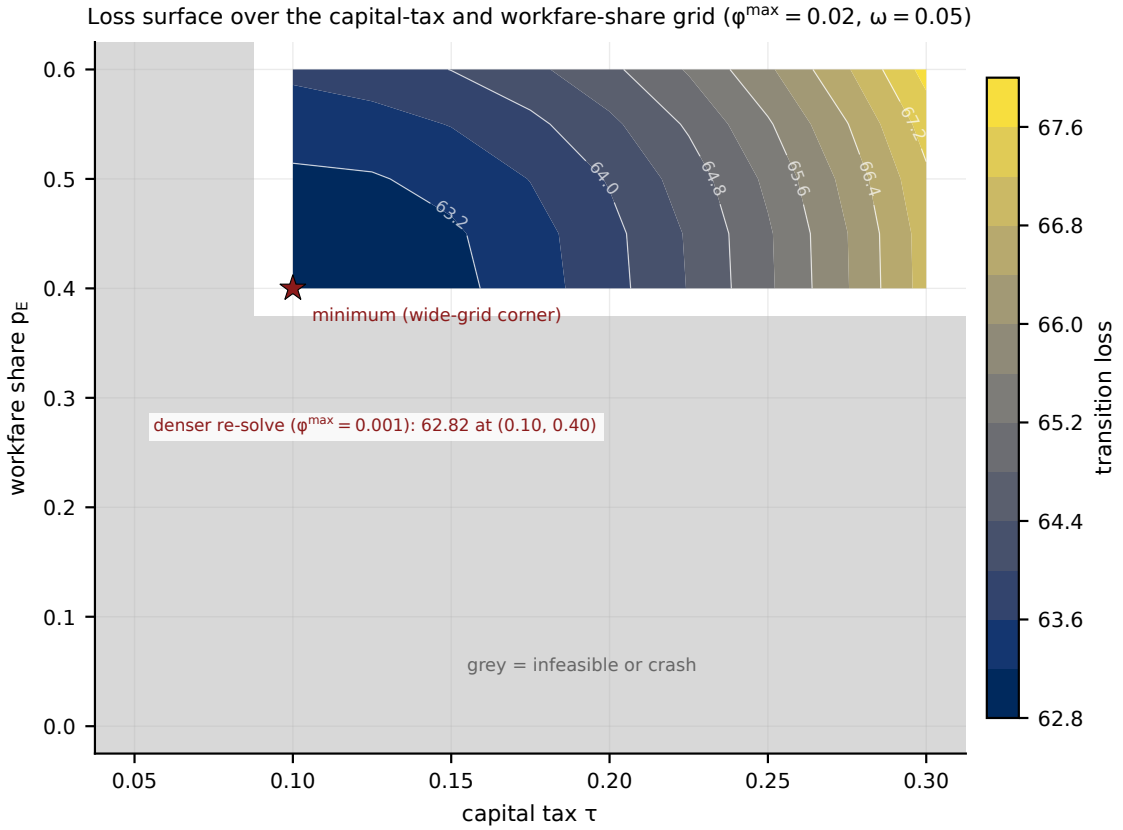

Figure 7: Transition loss over the capital-tax and workfare-share grid at $\phi^{\max} = 0.02$, $\omega = 0.05$. The grey region is infeasible (crash); the smooth region is confined to high workfare shares, and under the baseline loss weights the loss-minimizing point on this grid sits at its corner (solid star). The smooth surface is locally flat, so the minimizer's exact coordinates are grid-dependent rather than identified. A denser re-solve that extends $\phi^{\max}$ to 0.001 moves the minimizer to $(0.10, 0.40)$ with a loss of 62.82 (stated in the panel); that location is not a point on the $\phi^{\max} = 0.02$ surface drawn here, which is why it is reported in words rather than marked.

dominance is therefore a property of the model, while transfers being closed at the optimum is a property of the baseline weights and the lower grid bound.

Stochastic robustness. We shock the frontier growth, the parameter on which the smooth conclusion most depends, setting $g_{A,t} = 0.010 + \varepsilon_t$ with an AR(1) deviation ($\rho = 0.5$, Gaussian innovations of standard deviation σ_ε, distinct from the skill index σ_t); each configuration is run 200 times and a path is recorded as a crash when it triggers a crash test before the horizon. Table 5 reports the results.

Table 5: Monte Carlo crash counts under frontier-growth shocks (200 replications; AR(1), $\rho = 0.5$). Buffer is $\min_t C_t - 0.300$; the last column reports the fifth percentile of $\min_t C_t$ at $\sigma_\varepsilon = 0.03$.

Configuration	buffer	σ_ε=0.01	σ_ε=0.02	σ_ε=0.03	$\min_t C_t$, 5%
Headline $(0.15, 0.45, 0.02)$	0.056	0/200	0/200	0/200	0.354
Refined $(0.13, 0.44, 0.001)$	0.048	0/200	0/200	0/200	0.335

Two things follow. First, neither configuration crashes across the tested sizes, the bounded debt block and financed buffer defending consumption; with zero crashes in 200 draws, the Clopper–Pearson one-sided 95% upper bound on the true crash probability is 1.49%, so zero observed crashes does not establish a zero probability. At $\sigma_\varepsilon = 0.03$, 69 headline paths (65 refined) fail to reach the absorbing value within T and are right-censored, counted as neither survival nor crash. Second, the headline buffer of 0.056 holds the fifth-percentile minimum at 0.354, while the 0.048 refined buffer falls to 0.335, closer to the floor.

The deterministic v6 global-best point $(0.10, 0.40, 0.001)$ is not a third crash-free design: its buffer is only 0.010, and under the stochastic engine it crashes with 16, 58 and 74 paths and fifth-percentile minima of 0.298, 0.288 and 0.279, the floor breaking mid-horizon after skill depreciation. The refined point $(0.13, 0.44)$ keeps a 0.048 buffer and stays crash-free, so buffer thickness rather than the third decimal of the deterministic loss decides stochastic survival; demand-side, monetary and implementation shocks are not modelled, and a fully stochastic version remains for future work.

Two configurations, not one. The smooth headline depends on the public-employment intensity rather than the transfer ceiling. Under the standard setting, both workfare shares clear the floor ($\min C = 0.333$ and 0.358 at $p_E = 0.30$ and 0.45), and a higher share raises the margin; the sharp threshold for this calibration is $p_E = 0.1405$. The binding condition is therefore the workfare share, not a tight transfer ceiling.

Social-threshold sensitivity sweep. A dedicated sweep varies one social-channel parameter at a time (ς^{th}, α_s, J) under the calibrated parameters and compares the corner, the standard setting and the pure transfer; Table 6 reports baseline outcomes and Table 7 the boundaries.

Mechanism. At $p_E = 0.45$, only 55% of the unemployed remain on pure relief, so $\varsigma_t = 0.55\,\alpha_s u_t$, peaking at 0.330 at the baseline, which is 34% below the 0.50 cutoff; the analytic boundaries $\varsigma^{th}_{crit} = 0.33$ and

Figure 8: Isolation experiment: the loss saved by retraining Δ rises monotonically with the reinstatement rate ω, the share of new tasks accruing to labor. As $\omega \to 0$ (AGI takes over new-task creation and reinstatement fails), the value of retraining vanishes, confirming that skill retention pays off only while labor can still capture new tasks.

$\alpha_s^{crit} = 0.50/0.55 = 0.909$ are therefore exact. Under the pure transfer, 100% stay on relief and ς_t peaks at $\alpha_s = 0.60 > 0.50$, triggering the channel at the baseline.

Conditional conclusion. The ranking does not flip within the scanned range. To make the corner socially crash, ς^{th} must fall below 0.33 or α_s rise above 0.91, while the pure transfer already crashes at the baseline, and J is immaterial to the corner. The ranking remains conditional on the reduced-form cutoffs, with the external anchoring examined in Section 5.3.

Robustness to the functional form and to feedback. Replacing the linear conversion with $g(r) = r^{\gamma}$ gives critical α_s of 0.67, 0.91, and 1.65 across concave, linear and convex forms, the linear value matching the analytic 0.909, while the pure transfer critical value stays 0.50 under every form. Opening a pressure-to-output channel, the corner stays smooth throughout ($\min C = 0.326$ at full strength), the standard setting turns economic only at full strength, and the pure transfer crashes at every strength. Under both tests the workfare corner stays smooth while the pure transfer crashes, so the ranking is not an artifact of the linear, no-feedback law; the boundary moving from 0.67 to 1.65 is reported rather than absorbed.

5.3. External empirical anchoring of the social-instability parameters

The three social-instability parameters are reduced-form settings rather than externally identified quantities. The cutoff ς^{th} has no direct external anchor, while α_s and J are only partially anchored: crime semi-elasticities, kept in consistent units and combined with the model's own conversion, reverse-engineer a wide illustrative interval of about 1.0–6.6 for α_s, with the baseline 0.60 sitting below its lower end as

Table 6: Baseline social-channel outcomes ($\varsigma^{th} = 0.50, \alpha_s = 0.60, J = 10,\ g_A = 0.010$). Reported path statistics are rounded to three decimals.

Policy	outcome	crash type	$\min C$	peak stress	social crash
Corner $(0.15, 0.45, 0.02)$	smooth	none	0.357	0.330	no
Standard $(0.16, 0.45, 0.65)$	smooth	none	0.358	0.330	no
Pure transfer $(0.16, 0, 0.65)$	crash	both	0.259	0.600	yes

Table 7: Social-crash boundaries under one-at-a-time sweeps.

Swept parameter (baseline)	Corner	Standard	Pure transfer
critical ς^{th} (base 0.50)	0.33	0.33	0.60
critical α_s (base 0.60)	0.91	0.91	0.50
critical J (base 10)	never triggers	never triggers	all $J \in [3, 30]$

Values below/above the boundary trigger the social crash; for ς^{th} a lower value triggers, for α_s a higher value triggers.

a conservative setting, and $J = 10$ is a mean/upper-tail anchor drawn from crisis recovery and civil-war durations. The full literature review, the mapping assumptions and the empirical-range sweep are reported in Online Appendix C. The workfare-over-transfer ranking is conditional on these reduced-form cutoffs.

6. Contribution to the Literature

The analysis belongs to the structural-change tradition that treats technology-driven reallocation of the economy's composition, rather than a single aggregate equilibrium, as the central object. Pasinetti [43] builds growth on the changing sector composition induced by technical progress, so that structural dynamics precede aggregate analysis. Goodwin [44] casts employment and distribution as an endogenous nonlinear cycle, studied through dynamics rather than comparative statics. Baumol [45] shows how differential productivity growth across sectors produces structural imbalance and a persistent reallocation of labor. The present paper keeps the shared emphasis on technology-driven reallocation and nonlinear dynamics, but locates structural change at the task boundary between humans and AGI rather than at the sector boundary, and studies a case in which the reinstatement engine that reallocates displaced workers collapses endogenously rather than carrying labor through a smooth sectoral shift, with the fiscal and social safety nets closed explicitly. Against that background, the existing AGI macroeconomics literature addresses the transition along three separate axes. Restrepo (2025) and Korinek–Suh (2024) characterize the *supply-side* conditions under which automation

collapses wages; Fornaro–Wolf (2026) trace the *demand-side* channel from income shifts to the natural rate; and the fiscal-instrument literature treats taxes and transfers as optimal-schedule objects. Within the studies surveyed here, these axes are not decided together: the size and the financing of the buffer and the existence of the high-employment branch are typically treated as separate questions. This paper proposes a two-layer task model that:

1. **Endogenizes the reinstatement collapse** (driven by AGI participation κ_N^{AI} and the reinstatement rate ω), proving the labor share vanishes monotonically (Theorem 1), and shows skill-retention value decays with ω, with no value as $\omega \to 0$.
2. **Turns the Fornaro–Wolf demand shortfall into a decidable crash channel** (Theorem 5), linking it to the Theorem 1 collapse source.
3. **Characterizes the fiscal closure**: a Laffer interior tax τ^* (Proposition 8) and within-budget superiority of public employment over transfers (Proposition 9).
4. **Introduces a social-instability channel independent by construction, in a separate equation rather than through economic deflation**, proving under the assumed pressure law that workfare dominates the pure transfer for social-instability risk (Proposition 10), complementing the qualitative Tcherneva/Ravallion debate and the basic-income-versus-job-guarantee comparison of Mitchell and Watts [33, 27, 23].
5. **Establishes a robustness ceiling for the buffer family** (Proposition 11): strong shocks require supply-side structural measures, a result absent from the literature.
6. **States the bifurcation at two levels**. Acemoglu–Restrepo treat κ_N (in their notation) as an exogenous constant and leave its determinants open; we derive the fast subsystem directly from the model and show that the high-employment branch reaches and crosses the switching manifold through a persistence-type boundary equilibrium bifurcation in a frozen static slice, yielding a closed-form critical reinstatement rate together with the finite-rate lag between slow policy and fast employment. Because that branch is inadmissible under full substitution, we then pose the global outcome bifurcation under a full-absorption public-employment policy, locating the boundary between the crash basin and the smooth absorption basin by bisection (Section 4). Both reductions are static or model-implied statements whose parameters are dimensionless and illustrative rather than estimated; on a full path an effective fast-subsystem crossing flattens the labor-share decline discontinuously without interior convergence, so the claim is structural rather than quantitative.

Calibration anchors three magnitudes to data (the consumption floor, the transfer MPC and the workfare wage ratio); the initial labor share $s_0 = 0.90$ follows from the model's own task block, the U.S. labor share of 53.8% is a qualitative benchmark rather than a target, and the elasticity range and the -30%/yr compute-cost decline are background and enter no equation (Section 5). The grid search returns a "workfare-dominant +

capital-tax-financed" corner whose coordinates are grid-dependent rather than uniquely identified, providing an analyzable and quantitative basis for a consumption-smooth AGI transition.

Related empirical work grounds the task and labor-share foundations. The skill-content framework originates with Autor, Levy and Murnane [7], while the automation-versus-new-tasks view of skill bias is developed by Acemoglu and Restrepo [4]; exposure to robots is estimated to reduce local employment and wages [3]; and the globally declining labor share is documented by Karabarbounis and Neiman [19] and linked to the reallocation of value toward superstar firms [6]. Broader policy-oriented analyses emphasize the distributional harms of AI deployed along its current trajectory [1] and the need for development strategies that share the gains from artificial intelligence more widely [21].

Several recent papers address adjacent mechanisms, and in each case the difference lies along a specific axis. Atolia, Holland and Kreamer [5] solve for the majority-voting optimal capital tax and basic income after an episode of automation, characterizing long-run outcomes and transitional welfare. Their policy is an optimal tax–transfer schedule; ours treats the two instruments as parameters of a bifurcation unfolding and asks when the high-employment branch crosses the switching manifold. Kleven and Zidar [20] characterize optimal labor and capital income taxation in a task-based automation model calibrated to the U.S. wage distribution, and find a sizable optimal capital tax that is, in their benchmark, unaffected by automation. Our capital tax is not an optimal-tax object: it is the financing instrument of the buffer. In the simulated paths capital income $\Pi_t = \max\{0, Y_t - w_t L_t^D\}$ does not shrink as $s_t \to 0$; output growth outpaces the fall in the wage bill and Π_t widens rather than contracts. The binding constraint is therefore the period-by-period timing of revenue rather than a vanishing tax base: with no reserve account, period-t spending is limited to taxes already collected in $t-1$, so early in the transition, before the tax base has grown, planned spending is scaled down. The constraint we identify is this fiscal feasibility rather than tax optimality. Ray and Mookherjee [28] derive the long-run labor share in a growth framework where automation moves the share along a smooth path; we study the case in which the reinstatement engine itself collapses, so the share crosses the switching manifold through a boundary bifurcation rather than following a continuous decline. Nakamura and Zeira [24] analyze transitional unemployment dynamics and identify conditions under which assistance arrives in time; their object is the unemployment stock, ours is the existence of an equilibrium branch. Bond and Kremens [9] characterize income and inequality under asymptotically full automation, a steady-state distribution question, whereas our constraint is fiscal feasibility along the transition. Jacobs [17] studies capitalist–worker wealth distribution in a task-based model without a policy-instrument bifurcation, and Stiefenhofer [31] analyzes AGI substitution inside a CES production structure, where substitution is continuous across factors; our production structure is task-based, so substitution occurs at task boundaries and the resulting instability is discrete. Brault, Haghighi and Yang [16] study monetary policy in a two-sector New Keynesian model with downward nominal wage rigidity and show that accommodating AI-driven unemployment opens an intersectoral inflation wedge because one policy rate cannot clear both labor markets; their analysis is a single-instrument monetary trade-off, whereas our buffer is a fiscal instrument whose financing and the

existence of the high-employment branch are decided together.

7. Conclusion

This paper has integrated the supply, demand, fiscal and social sides of the AGI labor transition in one numerically solvable system. The mechanism group delivers the two failure modes, a monotonic labor-share collapse that under full substitution drives market employment to zero and makes a high-employment endpoint inadmissible within the model (the counterfactual evidence is compiled in Appendix Appendix A), together with a decidable demand-side spiral. The fiscal group verifies computationally that a financed buffer is nonempty, ranks workfare above transfers within the budget and under the assumed pressure law, and bounds the buffer at a ceiling beyond which only supply-side measures help. On the method, the fast-subsystem boundary equilibrium bifurcation gives a closed-form critical rate, and the global outcome bifurcation separates the crash and smooth full-absorption basins through two explicit gates. A fiscal gate on the consumption floor sets the boundary near $g_A = 0.095$ under $\tau = 0.15$, and once taxation is high enough that the fiscal gate no longer binds, a social gate sets an adjustment-speed boundary near 0.14, which is a minimum transition time rather than a fiscal or Laffer limit.

The policy implications follow within this calibrated model rather than as universal claims. At the baseline frontier growth, the smooth full-absorption path keeps minimum consumption at 0.407 as public employment rises to 0.85 and residual unemployment reaches zero, while the fixed corner holds consumption at 0.357 and the no-policy path crashes at 0.057. The loss-minimizing design is workfare-dominant and financed by a minimal sufficient capital tax. Transfers are costlier not only because of their MPC leakage: a same-budget comparison that reserves revenue for transfers and runs a genuine positive transfer flow lowers minimum consumption and contracts the critical frontier at every step, so the workfare ranking holds even when transfers actually spend money. The pure transfer and no-policy regimes are infeasible, the structural conditions being stated in Table 3, and the absorption is conditional on the automation pace, the fiscal base and the adjustment speed: under low taxation the floor is breached at the fiscal boundary near 0.095, whereas under high taxation the path is stopped at the adjustment-speed boundary near 0.14 even though consumption remains affordable. For sufficiently fast automation no demand-side absorption can keep pace within the model, so the response indicated by the model lies on the supply side. Read this way, the value of the exercise is present before the scenario arrives. Because the decisive instruments are slow and the boundary is a matter of speed, the practical output is a preparedness case rather than a forecast: building the fiscal base and the absorption mechanism in advance is what converts a high-impact scenario from a crash into a smooth path, whereas waiting for certainty removes the lead time on which the result depends.

Seven limitations point to future work. First, the social-instability channel is reduced-form and would benefit from a microfoundation in dignity and acceptability. Second, the reinstatement rate and the frontier growth require sharper empirical calibration. Third, the model is closed-economy and abstracts from monetary policy beyond the zero lower bound; monetary-fiscal interaction and open-economy flows are natural

extensions. Fourth, the core model is deterministic. The shock experiment finds neither configuration crashes at the tested scales while about a third of paths are right-censored rather than robust, and demand-side and policy-implementation shocks remain absent; a full stochastic version is left to future work. Fifth, the social-instability parameters lack strict external identification, the anchoring status and the empirical-range sweep being reported in Section 5.3, and the underlying empirical samples differ institutionally from the modeled setting. Sixth, both bifurcation results are model-implied rather than externally identified, the high-employment branch a counterfactual and the global boundary and p_E^* dimensionless outputs of the calibrated model. Seventh, the model is partial-equilibrium: after-tax capital income and the unconsumed transfer share are recorded as non-returning leakages, with no capital-owner recycling and an exogenous credit line. Endogenizing capital-owner demand and the funding side of credit requires explicit extension equations, with the sign of the effect on aggregate demand left to be determined rather than asserted, so the results are interpreted within this partial-equilibrium scope.

Funding

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Declaration of competing interest

The author declares that there are no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Declaration of generative AI and AI-assisted technologies in the writing process

During the preparation of this work the author used a generative AI assistant in order to improve the language and readability of the manuscript. After using this tool, the author reviewed and edited the content as needed and takes full responsibility for the content of the publication.

Appendix A. The high market-employment counterfactual

The body treats a high market-employment endpoint as a counterfactual under incomplete substitution. This appendix reports the falsification runs behind that classification rather than asserting it. The normative statement that AGI displaces every task under full substitution is Theorem 1; the question here is operational: across the full-substitution parameter domain, does any policy configuration hold the market share at a high level at the terminal date? A high market-employment endpoint is defined as a terminal market share at or

above 0.50. The full battery is reproduced by `analysis/check_high_employment_unreachable.py`, which exits with all checks passing.

Configuration (full substitution)	outcome	terminal s_L	terminal E^P
No policy ($\tau = 0.05, p_E = 0$)	crash	0.000	0.000
Workfare corner ($p_E = 0.45$)	smooth	0.004	0.448
Strong floor ($p_E = 0.80$, retrain 0.8)	not reached	0.338	0.529
All levers maxed ($p_E = 0.95$, retrain 1)	not reached	0.427	0.545
Full absorption	smooth	0.148	0.852
Exogenous reinstatement rate (incomplete-substitution counterfactual)			
$\omega = 0.30$	not reached	0.110	
$\omega = 0.50$	not reached	0.246	
$\omega = 0.70$	not reached	0.390	
$\omega = 0.90$	not reached	0.543	

Three facts follow. First, no configuration in the full-substitution domain reaches the 0.50 threshold; even with every policy lever raised at once the terminal share stays below 0.43. Second, the paths that stay smooth do so with a low terminal market share, the corner and full-absorption cases below 0.15, supported by public employment rather than by market jobs. Third, the high-employment share is recovered only by an exogenous high reinstatement rate, and the terminal share rises monotonically with that rate, crossing 0.50 near $\omega = 0.90$. A high market-employment attractor is therefore a property of the incomplete-substitution counterfactual rather than a reachable basin of the full-substitution model.

Appendix B. Fast-subsystem technical derivation

This appendix collects the algebra summarized in Section 4: the quadratic fast field, the switching manifold, the proof of the boundary equilibrium bifurcation, and the slow–fast reduction. The statements are the same as in the body; only the intermediate steps are moved here.

B.1 Normalization and the quadratic vector field.. Freeze the slowly evolving state and normalize

$$k_h = \frac{\kappa_N^h}{N}, \qquad q_A = \kappa_N^{AI} M_0, \qquad \mu = \frac{A}{N}, \qquad s = \frac{n}{N}, \qquad \sigma = \text{skill},$$

so the task and labor-task growth are

$$\frac{\dot{N}}{N} = k_h S_0\big(1 - \lambda_h(1-s)\big) + q_A \mu, \qquad \frac{\dot{n}}{N} = \omega\sigma\,\frac{\dot{N}}{N} - \kappa_I \mu.$$

Using the direct automation flow that binds in the high-employment region and $\dot{s} = \dot{n}/N - s\,\dot{N}/N$, expansion gives the fast field

$$\dot{s} = f_1(s) = -Cs^2 + Bs + A,$$

with coefficients

$$C = k_h S_0 \lambda_h > 0, \qquad \Xi = k_h S_0 (1 - \lambda_h) < 0,$$
$$B = C\omega\sigma - \Xi - q_A\mu, \qquad A = \omega\sigma(\Xi + q_A\mu) - \kappa_I\mu.$$

The leading nonlinearity is quadratic and $f_1'''(s) \equiv 0$, so no cubic coefficient on which a cusp normal form would rest is induced. The generic unfolding of a one-dimensional quadratic field is fold-type, but the event is located here by the boundary of the admissible state space rather than by an interior discriminant.

B.2 The switching manifold.. The truncated human share $S^h(s) = S_0 \max\{0, 1 - \lambda_h(1 - s)\}$ is positive only above $s_{\text{floor}} = 1 - 1/\lambda_h$. Below it the human share is identically zero and the second-region field is linear,

$$\dot{s} = f_2(s) = \mu\big(\omega\sigma q_A - \kappa_I - q_A s\big).$$

The fields join continuously on the manifold, and direct subtraction gives the constant jump

$$f_1'(s_{\text{floor}}) - f_2'(s_{\text{floor}}) = k_h S_0\big(\lambda_h\omega\sigma - \lambda_h + 1\big), \tag{B.1}$$

so the fast subsystem is a continuous piecewise-smooth Filippov system, C^0 but not C^1.

B.3 Proof of the boundary equilibrium bifurcation.. On the manifold,

$$f_1(s_{\text{floor}}) = f_2(s_{\text{floor}}) = \mu\big(\omega\sigma q_A - \kappa_I - q_A s_{\text{floor}}\big). \tag{B.2}$$

For $\mu > 0$ the condition $f_1(s_{\text{floor}}) = 0$ is equivalent to $\omega\sigma = \kappa_I/q_A + s_{\text{floor}}$, giving $\omega_c = \sigma^{-1}(\kappa_I/q_A + s_{\text{floor}})$. Differentiating (B.2) in ω gives $\partial_\omega f_1(s_{\text{floor}}) = \mu q_A \sigma > 0$, which establishes transversality. The unique region-II equilibrium of f_2 is

$$s^{**} = \omega\sigma - \frac{\kappa_I}{q_A},$$

which equals s_{floor} at ω_c and lies below the manifold for $\omega < \omega_c$. At the boundary equilibrium the region-II slope is $f_2'(s_{\text{floor}}) = -q_A\mu < 0$, and using (B.1) at the critical value the region-I slope is

$$f_1'(s_{\text{floor}}) = -q_A\mu + \frac{C\kappa_I}{q_A}.$$

It is negative exactly under $q_A\mu > C\kappa_I/q_A$. When this persistence condition holds, both one-sided slopes are negative and the equilibrium crosses with stability preserved, the persistence-type BEB; if it fails, the region-I branch is repelling and the event is not of persistence type. The hard lower boundary contributes the entry threshold $\omega_0^{(\text{entry})} = \sigma^{-1}\kappa_I/q_A$ at which $s^{**} = 0$; below it the physical state space contains no equilibrium and the trajectory is absorbed at $s = 0$.

B.4 Multiple time scales and the finite-rate lag (discrete time).. The engine is a discrete recursion. Within each period the rate is updated first, $\omega_t = \text{logit}^{-1}(\ell_0 + \Gamma_t - \beta_A g_t)$, and the employment share is then updated from the task accounts, so the share responds to the rate already realized in the same period rather than to a future value. The logistic compresses ω near its bounds, which makes its per-period change small on weak-policy paths and leaves the share tracking a moving target with a one-period lag; on strong-policy paths the two changes are comparable, so the separation is path-dependent and measured, not imposed. No continuous parameter ε is defined and the continuous-time Fenichel theory is used only as a conceptual reference, not as a theorem of this recursion. Crossing the switching manifold still changes the tracking slope discontinuously. The static interior equilibrium is not by itself an attractor of the full model; on a full path the verified signature of an effective crossing is a discontinuous flattening of the market-share slope, not a reversal or interior convergence.
